Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Previous editions copyrighted in 2012, 2005, 1998, 1991, 1984, 1977, 1971, 1965, 1960.

Library of Congress Cataloging-in-Publication Data

Names: Gleason, Christine A., editor. | Juul, Sandra E., editor.
Title: Avery's diseases of the newborn / [edited by] Christine A. Gleason, Sandra E. Juul.
Other titles: Diseases of the newborn
Description: Tenth edition. | Philadelphia, PA : Elsevier, [2018] | Includes bibliographical references and index.
Identifiers: LCCN 2017019069 | ISBN 9780323401395 (hardcover : alk. paper)
Subjects: | MESH: Infant, Newborn, Diseases
Classification: LCC RJ254 | NLM WS 421 | DDC 618.92/01--dc23

*To the babies—our patients—who humble and inspire us.
To their families, who encourage us to keep moving our field forward.
To neonatal caregivers everywhere, with gratitude for all you do.*

Contributors

Steven H. Abman, MD

Professor
Department of Pediatrics
University of Colorado Health Sciences Center
Director
Pediatric Heart Lung Center
The Children's Hospital
Aurora, Colorado

Karel Allegaert, MD, PhD

Professor
Department of Woman and Child
KU Leuven
Leuven, Belgium
Consultant
Department of Surgery and Intensive Care
Erasmus MC-Sophia Children's Hospital
Rotterdam, The Netherlands

Bhawna Arya, MD

Assistant Professor
Department of Pediatrics and Pediatric Cardiology
University of Washington
Seattle Children's Hospital
Seattle, Washington

David Askenazi, MD, MSPH

Associate Professor
Department of Pediatrics
University of Alabama at Birmingham
Birmingham, Alabama

Timur Azhibekov, MD

Assistant Professor of Clinical Pediatrics
Fetal and Neonatal Institute
Division of Neonatology
Children's Hospital of Los Angeles
Department of Pediatrics
Keck School of Medicine
University of Southern California, Los Angeles
Los Angeles, California

Stephen A. Back, MD, PhD

Professor of Pediatrics and Neurology
Oregon Health and Science University
Clyde and Elda Munson Professor of Pediatric Research
Director
Neuroscience Section
Papé Family Pediatric Research Institute
Portland, Oregon

H. Scott Baldwin, MD

Professor of Pediatrics and Cell and Developmental Biology
Vanderbilt University Medical Center
Chief
Division of Pediatric Cardiology
Co-Director
Pediatric Heart Institute
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

Roberta A. Ballard, MD

Professor
Department of Pediatrics and Neonatology
University of California, San Francisco, School of Medicine
San Francisco, California

Eduardo Bancalari, MD

Professor of Pediatrics
Director
Division of Neonatology
University of Miami Miller School of Medicine
Chief
Newborn Service
Jackson Memorial Hospital
Miami, Florida

Carlton M. Bates, MD

Professor of Pediatrics
Vice Chair for Basic Research
Department of Pediatrics
University of Pittsburgh School of Medicine
Chief of Pediatric Nephrology
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Maneesh Batra, MD, MPH

Associate Professor
Department of Pediatrics
University of Washington School of Medicine
Seattle, Washington

Cheryl B. Bayart, MD, MPH

Department of Pediatric Dermatology
University of Washington
Seattle Children's Hospital
Seattle, Washington

Gary A. Bellus, MD, PhD

Associate Professor
Department of Pediatrics and Dermatology
University of Colorado School of Medicine
Aurora, Colorado
Director
Clinical Genetics and Genomic Medicine
Geisinger Health System
Danville, Pennsylvania

Thomas J. Benedetti, MD, MHA

Professor
Department of Obstetrics and Gynecology
University of Washington School of Medicine
Seattle, Washington

John T. Benjamin, MD, MPH

Assistant Professor of Pediatrics
Department of Pediatrics
Division of Neonatology
Vanderbilt University Medical Center
Nashville, Tennessee

James T. Bennett, MD, PhD

Assistant Professor of Pediatrics
Division of Genetic Medicine
Center for Developmental Biology and Regenerative
Medicine
Assistant Director
Molecular Diagnostic Laboratories
University of Washington
Seattle Children's Hospital
Seattle, Washington

Gerard T. Berry, MD

Harvey Levy Chair in Metabolism
Director
Metabolism Program
Division of Genetics and Genomics
Boston Children's Hospital
Professor of Pediatrics
Harvard Medical School
Boston, Massachusetts

Gil Binenbaum, MD, MSCE

Attending Surgeon
Department of Ophthalmology
The Children's Hospital of Philadelphia
Associate Professor of Ophthalmology
Department of Ophthalmology
Perelman School of Medicine at the University of
Pennsylvania
Philadelphia, Pennsylvania

Markus D. Boos, MD, PhD

Assistant Professor
Department of Pediatrics
Division of Dermatology
University of Washington
Seattle Children's Hospital
Seattle, Washington

Maryse Bouchard, MD, MSc

Associate Professor
Orthopaedic Surgery
University of Washington
Pediatric Orthopedic Surgeon
Department of Orthopedics and Sports Medicine
Seattle Children's Hospital
Seattle, Washington

Heather A. Brandling-Bennett, MD

Associate Professor
Department of Pediatrics
University of Washington
Seattle Children's Hospital
Seattle, Washington

Darcy E. Broughton, MD

Clinical Fellow
Department of Obstetrics and Gynecology
Division of Reproductive Endocrinology and Infertility
Washington University in St. Louis
St. Louis, Missouri

Zane Brown, MD

Professor
Division of Perinatology
Department of Obstetrics and Gynecology
Division of Women's Health
University of Washington
Seattle, Washington

Katherine H. Campbell, MD, MPH

Assistant Professor
Department of Obstetrics, Gynecology, and Reproductive
Sciences
Yale University School of Medicine
New Haven, Connecticut

Suzan L. Carmichael, PhD, MS

Professor
Department of Pediatrics
Stanford University
Stanford, California

Brian S. Carter, MD

Professor of Pediatrics
Division of Neonatology
University of Missouri-Kansas City School of Medicine
Bioethicist
Bioethics Center
Children's Mercy Hospital
Kansas City, Missouri

Stephen Cederbaum, MD

Research Professor
Department of Psychiatry, Pediatrics, and Human Genetics
University of California, Los Angeles
Los Angeles, California

Shilpi Chabra, MD

Associate Professor
Department of Pediatrics
University of Washington and
Seattle Children's Hospital
Seattle, Washington

Justine Chang, MD

Assistant Professor
Department of Obstetrics and Gynecology
University of Washington
Seattle, Washington

Edith Y. Cheng, MD, MS

Professor
Chief of Service
Obstetrics
Division Chief
Maternal Fetal Medicine
Department of Maternal Fetal Medicine and Medical Genetics
University of Washington
Seattle, Washington

Karen M. Chisholm, MD, PhD

Anatomic Pathologist
Department of Laboratories
Seattle Children's Hospital
Clinical Assistant Professor
Department of Laboratory Medicine
University of Washington
Seattle, Washington

Robert D. Christensen, MD

Robert L. Jung Presidential Chair
Professor and Division Chief
Division of Neonatology
Professor
Division of Hematology/Oncology
University of Utah School of Medicine
Director of Research

Intermountain Healthcare
Salt Lake City, Utah

Terrence Chun, MD

Associate Professor of Pediatrics
Department of Pediatrics
University of Washington
Seattle, Washington

Nelson Claude, MSc, PhD

Research Associate Professor
Director
Neonatal Pulmonary Research Laboratory
Department of Pediatrics
Division of Neonatology
University of Miami Miller School of Medicine
Miami, Florida

Ronald I. Clyman, MD

Professor of Pediatrics and Senior Staff
Cardiovascular Research Institute
University of California, San Francisco
San Francisco, California

Tarah T. Colaizy, MD, MPH

Associate Professor of Pediatrics
Stead Department of Pediatrics
University of Iowa
Iowa City, Iowa

DonnaMaria E. Cortezzo, MD

Assistant Professor
Pediatrics and Anesthesiology
Division of Neonatology and Pulmonary Biology
Division of Pediatric Palliative Care
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

C. Michael Cotten, MD, NHS

Professor of Pediatrics
Department of Pediatrics and Neonatology
Duke University School of Medicine
Durham, North Carolina

Michael L. Cunningham, MD, PhD

Professor and Chief
Division of Craniofacial Medicine
Department of Pediatrics
University of Washington
Medical Director
Craniofacial Center
Seattle Children's Hospital
Seattle, Washington

Alejandra G. de Alba Campomanes, MD, MPH

Associate Professor of Clinical Ophthalmology and Pediatrics
Department of Ophthalmology
University of California, San Francisco
San Francisco, California

Ellen Dees, MD

Assistant Professor of Pediatrics
Pediatric Cardiology Training Program
Vanderbilt Children's Hospital
Nashville, Tennessee

Sara B. DeMauro, MD, MSCE

Assistant Professor of Pediatrics
University of Pennsylvania Perelman School of Medicine
Program Director
Neonatal Follow-Up and Attending Neonatologist
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Scott C. Denne, MD

Professor of Pediatrics
Department of Pediatrics
Indiana University
Indianapolis, Indiana

Emöke Deschmann, MD, MMSc

Faculty/Attending Neonatologist
 Department of Women's and Children's Health
 Division of Neonatology
 Karolinska Institute
 Department of Neonatology
 Karolinska University Hospital
 Stockholm, Sweden

Carolina Cecilia DiBlasi, MD

Clinical Assistant Professor
 Division of Endocrinology and Diabetes
 University of Washington
 Seattle Children's Hospital
 Seattle, Washington

Robert M. DiBlasi, RRT-NPS, FAARC

Respiratory Research Coordinator
 Center for Developmental Therapeutics
 Seattle Children's Research Institute
 Seattle, Washington

Reed A. Dimmitt, MD, MSPH

Associate Professor of Pediatrics and Surgery
 Director
 Division of Neonatology and Pediatric Gastroenterology and Nutrition
 University of Alabama at Birmingham
 Birmingham, Alabama

Sara A. DiVall, MD

Assistant Professor
 Department of Pediatrics and Endocrinology
 University of Washington
 Seattle, Washington

Orchid Djahangirian, BSc, MD, FRCSC

Fellow
 Department of Pediatric Urology
 University of California, Irvine
 Irvine, California

Dan Doherty, MD, PhD

Professor
 Department of Pediatrics
 University of Washington
 Seattle Children's Hospital
 Seattle, Washington

Eric C. Eichenwald, MD

Professor of Pediatrics
 Department of Pediatrics
 Perelman School of Medicine at the University of Pennsylvania
 Chief
 Division of Neonatology
 Children's Hospital of Philadelphia
 Philadelphia, Pennsylvania

Rachel Engen, MD

Ann and Robert H. Lurie Children's Hospital of Chicago
 Chicago, Illinois

Cyril Engmann, MBBS, FAAP

Attending Neonatologist and Professor
 Department of Pediatrics and Global Health
 University of Washington Schools of Medicine and Public Health
 Global Program Leader and Director
 Maternal, Newborn, Childhealth, and Nutrition PATH
 Seattle, Washington

Jacquelyn R. Evans, MD

Associate Division Chief of Neonatology
 Department of Pediatrics
 Children's Hospital of Philadelphia and
 Perelman School of Medicine at the University of Pennsylvania
 Chair
 The Children's Hospital Neonatal Consortium
 Philadelphia, Pennsylvania

Kelly N. Evans, MD

Assistant Professor
 Department of Pediatrics
 University of Washington
 Craniofacial Center
 Seattle Children's Hospital
 Seattle, Washington

Diana L. Farmer, MD, FACS, FRCS

Professor and Chair
 Surgeon-in-Chief
 Department of Surgery
 University of California, Davis
 Sacramento, California

Patricia Y. Fechner, MD

Medical Director
 DSD Program
 Seattle Children's Hospital
 Professor
 Department of Pediatric Endocrinology
 University of Washington School of Medicine
 Seattle, Washington

Patricia Ferrieri, MD

Chairman's Fund Endowed Professor in Laboratory Medicine and Pathology
 Professor
 Department of Pediatrics
 Division of Infectious Diseases
 University of Minnesota Medical School
 Director
 Infectious Diseases Diagnostic Laboratory
 University of Minnesota Medical Center
 Minneapolis, Minnesota

Neil N. Finer, MD

Division of Neonatal-Perinatal Medicine
 Department of Pediatrics
 University of California, San Diego
 San Diego, California

Rachel A. Fleishman, MD

Penn Medical Clinician
University of Pennsylvania School of Medicine
Attending Neonatologist
CHOP Newborn Care Network
Children's Hospital of Pennsylvania
Philadelphia, Pennsylvania

Bobbi Fleiss, PhD

Division of Imaging Sciences and Biomedical Engineering
King's College London
London, Great Britain

Joseph T. Flynn, MD, MS

Dr. Robert O. Hickman Endowed Chair in Pediatric Nephrology
Professor of Pediatrics
University of Washington
Chief
Division of Nephrology
Seattle Children's Hospital
Seattle, Washington

Katherine T. Flynn-O'Brien, MD, MPH

Resident Physician
Department of Surgery
University of Washington
Seattle, Washington

Mark R. Frey, PhD

Associate Professor
Department of Pediatrics, and Biochemistry and Molecular
Medicine
The Saban Research Institute of Children's Hospital
University of Southern California, Los Angeles
Los Angeles, California

Lydia Furman, MD

Professor of Pediatrics
Rainbow Babies and Children's Hospital
Co-Chair
UHCMC Institutional Review Board
Case Western Reserve University School of Medicine
Cleveland, Ohio

Renata C. Gallagher, MD, PhD

Professor of Clinical Pediatrics
Department of Pediatrics
University of California, San Francisco
San Francisco, California

Estelle B. Gauda, MD

Professor of Pediatrics
Department of Pediatrics
The Johns Hopkins University School of Medicine
Baltimore, Maryland

Christine A. Gleason

Professor of Pediatrics
Division of Neonatology
Department of Pediatrics
University of Washington
Seattle Children's Hospital
Seattle, Washington

Michael J. Goldberg, MD

Clinical Professor
Department of Orthopaedics and Sports Medicine
University of Washington
Seattle Children's Hospital
Seattle, Washington

Adam B. Goldin, MD, MPH

Associate Professor
Department of Pediatric General and Thoracic Surgery
University of Washington
Seattle Children's Hospital
Seattle, Washington

Sidney M. Gospe, Jr., MD, PhD

Herman and Faye Sarkowsky Endowed Chair of Child
Neurology
Professor
Department of Neurology and Pediatrics
University of Washington
Head
Division of Neurology
Seattle Children's Hospital
Seattle, Washington

Pierre Gressens, MD, PhD

Research Officer and Director
Robert-Debre Hospital
Paris, France

Deepti Gupta, MD

Assistant Professor
Department of Pediatrics
Division of Dermatology
University of Washington
Seattle Children's Hospital
Seattle, Washington

Susan H. Guttentag, MD

Julia Carell Stadler Professor of Pediatrics
Department of Pediatrics
Division of Neonatology
Monroe Carell, Jr., Children's Hospital at Vanderbilt
Nashville, Tennessee

Chad R. Haldeman-Englert, MD

Clinical Geneticist
Fullerton Genetics Center
Asheville, North Carolina

Thomas N. Hansen, MD

Senior Investigator
Center for Developmental Therapeutics
Seattle Children's Research Institute
Seattle, Washington

Anne V. Hing, MD

Professor
Department of Pediatrics
University of Washington
Seattle, Washington

Sangeeta Hingorani, MD, MPH

Associate Professor
Department of Pediatrics
University of Washington
Seattle Children's Hospital
Assistant Member
Clinical Research Division
Fred Hutchinson Cancer Research Center
Seattle, Washington

Susan R. Hintz, MD, MS

Robert L. Hess Family Professor
Professor of Pediatrics, and Obstetrics and Gynecology
Associate Chief for Prenatal Services
Division of Neonatal and Developmental Medicine
Stanford University School of Medicine
Medical Director
Fetal and Pregnancy Health Program
Lucile Packard Children's Hospital
Palo Alto, California

Shinjiro Hirose, MD

Associate Professor and Division Chief
Pediatric General, Thoracic, and Fetal Surgery
Department of Surgery
University of California, Davis
Sacramento, California

W. Alan Hodson, MMSc, MD

Professor Emeritus
Department of Pediatrics
University of Washington
Seattle, Washington

Kara K. Hoppe, DO

Department of Obstetrics and Gynecology
Maternal Fetal Medicine
University of Wisconsin-Madison
Madison, Wisconsin

Margaret K. Hostetter, MD

BK Rachford Professor and Chair
Department of Pediatrics
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Benjamin Huang, MD

Clinical Instructor
Department of Pediatrics
University of California, San Francisco
San Francisco, California

Sarah Bauer Huang, MD, PhD

Child Neurology Resident
Department of Neurology
University of Washington
Seattle, Washington

Terrie E. Inder, MBChB, MD

Cristian Ionita
Department of Neurology
University of Washington
Seattle Children's Hospital
Seattle, Washington

Cristian Inoita, MD

Clinical Associate Professor
Department of Pediatrics
Yale University School of Medicine
New Haven, Connecticut

J. Craig Jackson, MD, MHA

Professor
Department of Pediatrics
University of Washington
Seattle Children's Hospital
Seattle, Washington

Deepak Jain, MD

Assistant Professor of Pediatrics
Department of Pediatrics
Division of Neonatology
University of Miami Miller School of Medicine
Jackson Memorial Hospital
Miami, Florida

Lucky Jain, MD, MBA

Richard W. Blumberg Professor and Chairman
Department of Pediatrics
Emory University School of Medicine
Chief Academic Officer
Children's Healthcare of Atlanta
Atlanta, Georgia

Patrick J. Javid, MD

Associate Professor of Surgery
Department of Surgery
University of Washington
Pediatric Surgeon
Seattle Children's Hospital
Seattle, Washington

Cassandra D. Josephson, MD

Associate Professor
Pathology and Pediatrics
Director Clinical Research
Department of Pathology
Center for Transfusion and Cellular Therapies
Director
Transfusion Medicine Fellowship Program
Department of Pathology
Center for Transfusion and Cellular Therapies
Emory University School of Medicine
Medical Director
Pathology Department
Blood and Tissue Services
Children's Healthcare of Atlanta
Atlanta, Georgia

Emily S. Jungheim, MD, MSCI

Assistant Professor
Department of Obstetrics and Gynecology
Division of Reproductive Endocrinology and Infertility
Washington University in St. Louis
St. Louis, Missouri

Sandra E. Juul, MD, PhD

W. Alan Hodson Endowed Chair in Pediatrics
Professor of Pediatrics
Chief
Division of Neonatology
Department of Pediatrics
University of Washington
Seattle Children's Hospital
Seattle, Washington

Anup Katheria, MD, FAACP

Assistant Professor of Pediatrics
Department of Pediatrics
Loma Linda University
Loma Linda, California
Director
Neonatal Research Institute
Sharp Mary Birch Hospital for Women and Newborns
San Diego, California

Benjamin A. Keller, BS, MD

Chief Surgical Resident
Department of Surgery
University of California, Davis
Sacramento, California

Roberta L. Keller, MD

Professor of Clinical Pediatrics
Vice Chair
Clinical Translational Research
Director of Neonatal Research
Director
Neonatal ECMO Program
Director of Neonatal Services
Fetal Treatment Center
UCSF Benioff Children's Hospital
University of California, San Francisco
San Francisco, California

Thomas F. Kelly, MD

Clinical Professor and Chief
Division of Perinatal Medicine
Department of Reproductive Medicine
University of California, San Diego
School of Medicine
La Jolla, California
Director of Maternity Services
University of California, San Diego Medical Center
San Diego, California

Kate Khorsand, MD

Department of Pediatrics
Division of Dermatology
Seattle Children's Hospital
Seattle, Washington

Grace Kim, MD, MS

Assistant Professor
Department of Endocrinology
Seattle Children's Hospital
Seattle, Washington

John P. Kinsella, MD

Professor
Department of Pediatrics
University of Colorado School of Medicine
Children's Hospital Colorado
Aurora, Colorado

Ildiko H. Koves, MD, FRACP

Associate Professor
Department of Endocrinology and Diabetes
Seattle Children's Hospital
Seattle, Washington

Christina Lam, MD

Assistant Professor
Biochemical Genetics
Department of Pediatrics
Division of Genetic Medicine
University of Washington
Seattle Children's Hospital
Seattle, Washington
Guest Researcher
NIH, NHGRI
Bethesda, Maryland

Erin R. Lane, MD

Fellow
Pediatric Gastroenterology
University of Washington
Seattle, Washington

John D. Lantos, MD

Professor
Department of Pediatrics
University of Missouri–Kansas City
Kansas City, Missouri

Daniel J. Ledbetter, MD

Professor
Department of Surgery
University of Washington
Attending Surgeon
Department of Pediatric General and Thoracic Surgery
Seattle Children's Hospital
Seattle, Washington

Ben Lee, MD, MPH, MSCR

Associate Professor of Clinical Pediatrics
Weill Cornell Medicine-Qatar
Medical Director of Operations
Division of Neonatal and Perinatal Medicine
Sidra Medical and Research Center
Doha, Qatar

Harvey L. Levy, MD

Senior Physician in Medicine/Genetics
Division of Genetics and Genomics
Boston Children's Hospital
Professor of Pediatrics
Harvard Medical School
Boston, Massachusetts

Ofer Levy, MD, PhD

Principal Investigator
Precision Vaccines Program
Division of Infectious Diseases
Boston Children's Hospital
Associate Professor
Department of Human Biology and Translational Medicine
Harvard Medical School
Boston, Massachusetts

Mark B. Lewin, MD

Professor and Division Chief
Department of Pediatric Cardiology
University of Washington School of Medicine
Seattle, Washington

David B. Lewis, MD

Professor of Pediatrics
Chief
Division of Immunology and Allergy
Department of Pediatrics
Stanford University School of Medicine
Stanford, California
Attending Physician
Lucile Salter Packard Children's Hospital
Palo Alto, California

P. Ling Lin, MD, MSc

Associate Professor
Director
Pediatric Infectious Diseases Fellowship Program
Department of Pediatrics
Division of Infectious Diseases
Children's Hospital of Pittsburgh of UPMC
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Tiffany Fangtse Lin, MD

Pediatric Hematology Oncology Adjunct Instructor
Department of Pediatrics
University of California, San Francisco
San Francisco, California

Scott A. Lorch, MD, MSCE

Associate Professor
Department of Pediatrics
Perelman School of Medicine of the University of Pennsylvania
Harriet and Ronald Lassin Endowed Chair in Pediatric Neonatology
Director
Neonatal-Perinatal Medicine Fellowship
Division of Neonatology
Director
Center for Perinatal and Pediatric Health Disparities Research
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Akhil Maheshwari, MD

Professor of Pediatrics and Molecular Medicine
Pamela and Leslie Muma Endowed Chair in Neonatology
Chief
Division of Neonatology
Assistant Dean
Graduate Medical Education
Department of Pediatrics
University of South Florida
Tampa, Florida

Emin Maltepe, MD, PhD

Associate Professor
Department of Pediatrics, Biomedical Sciences, and
Developmental and Stem Cell Biology
Division of Neonatology
University of California, San Francisco
San Francisco, California

Ketzela J. Marsh, MS, MD

Fellow in Pediatric and Adult Infectious Diseases
University of Minnesota Medical School and Masonic
Children's Hospital
Minneapolis, Minnesota

Richard J. Martin, MBBS

Professor
Department of Pediatrics, Reproductive Biology, and Physiology
and Biophysics
Case Western Reserve University School of Medicine
Drusinsky/Fanaroff Professor
Department of Pediatrics
Rainbow Babies and Children's Hospital
Cleveland, Ohio

Dennis E. Mayock, BS, MD

Professor
Department of Pediatrics
University of Washington
Seattle, Washington

Ryan Michael McAdams, MD

Associate Professor
Department of Pediatrics
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Irene McAleer, MD, JD, MBA

Health Sciences Clinical Professor of Urology
Departments of Urology and Pediatric Urology
University of California, Irvine
Irvine, California

Steven J. McElroy, MD

Associate Professor
Interim Division Director
Departments of Pediatrics, and Microbiology and
Immunology
University of Iowa
Iowa City, Iowa

Kera M. McNelis, MD

Fellow
Department of Neonatology
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Patrick McQuillen, MD

Professor of Pediatrics & Neurology
Department of Pediatrics
University of California, San Francisco
San Francisco, California

William L. Meadow, MD, PhD

Professor
Department of Pediatrics
University of Chicago
Chicago, Illinois

Paul A. Merguerian, MD, MS

Professor
Department of Urology
University of Washington
Chief
Division of Urology
Seattle Children's Hospital
Seattle, Washington

Lina Merjane, MD

Assistant Professor
Department of Pediatrics and Endocrinology
University of Washington
Seattle, Washington

J. Lawrence Merritt, II, MD

Associate Professor
Department of Pediatrics
University of Washington
Seattle, Washington

Valerie Mezger, PhD

CNRS
Epigenetics and Cell Fate
Univ Paris Diderot, Sorbonne Paris Cité
Département Hospitalo-Universitaire PROTECT
Paris, France

Marian G. Michaels, MD, MPH

Professor of Pediatrics and Surgery
Division of Pediatric Infectious Diseases
Children's Hospital of Pittsburgh of UPMC
Professor of Pediatrics and Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Steven P. Miller, MDCM, MAAS

Division Head
Department of Pediatrics
Division of Neurology
The Hospital for Sick Children
Professor of Pediatrics
Department of Pediatrics
University of Toronto
Senior Scientist
Neuroscience and Mental Health
Sick Kids Research Institute
Chair in Pediatric Neuroscience
Bloorview Children's Hospital
Toronto, Ontario, Canada

Sowmya S. Mohan, MD

Assistant Professor
Department of Pediatrics
Division of Neonatal-Perinatal Medicine
Emory University
Atlanta, Georgia

Professor
Department of Pediatrics
The University of Iowa
Iowa City, Iowa

Karen F. Murray, MD

Chief
Division of Gastroenterology and Hepatology
Department of Pediatrics
Seattle Children's Hospital
Seattle, Washington

Debika Nandi-Munshi, MD

Assistant Clinical Professor
Department of Pediatric Endocrinology and Diabetes
Seattle Children's Hospital
University of Washington
Seattle, Washington

Niranjana Natarajan, MD

Assistant Professor
Department of Neurology
Division of Child Neurology
University of Washington
Seattle, Washington

Jeffrey J. Neil, MD, PhD

Professor of Neurology
Department of Neurology
Boston Children's Hospital
Boston, Massachusetts

Kathryn D. Ness, MD, MSCI

Clinical Associate Professor
Department of Pediatrics
Seattle Children's Hospital
Seattle, Washington

Josef Neu, MD

Professor
Department of Pediatrics
University of Florida
Gainesville, Florida

Angel Siu-Ying Nip, MBChB

Fellow
Department of Endocrinology
Seattle Children's Hospital
Seattle, Washington

Shahab Noori, MD

Associate Professor of Pediatrics
Fetal and Neonatal Institute
Division of Neonatology
Children's Hospital Los Angeles
Department of Pediatrics
Keck School of Medicine
University of Southern California
Los Angeles, California

Lila O'Mahony, MD

Clinical Assistant Professor
Department of Pediatric Emergency Medicine
University of Washington
Seattle Children's Hospital
Seattle, Washington

Jonathan P. Palma, MD, MS

Clinical Assistant Professor
Department of Pediatrics
Stanford University School of Medicine
Medical Director of Clinical Informatics
Stanford Children's Health Clinical Informatics Fellowship
Program Director
Stanford Medicine
Palo Alto, California

Nigel Paneth, MD, MPH

University Distinguished Professor
Department of Epidemiology and Biostatistics and Pediatrics
and Human Development
Michigan State University
East Lansing, Michigan

Thomas A. Parker, MD

Professor
Department of Pediatrics
University of Colorado School of Medicine
Children's Hospital of Colorado
Aurora, Colorado

Ravi Mangal Patel, MD

Associate Professor
Department of Pediatrics
Emory University School of Medicine
Children's Healthcare of Atlanta
Atlanta, Georgia

Anna A. Penn, MD, PhD

Associate Professor
Department of Pediatrics
George Washington University School of Medicine
Attending Physician
Director of Translational Research for Hospital-Based Services
Co-Director of Cerebral Palsy Prevention Program
Fetal and Transitional Medicine, Neonatology
Children's National Medical Center
Investigator
Children's Research Institute Center for Neuroscience
Children's National Medical Center
Washington, DC

Christian M. Pettker, MD

Associate Professor
Department of Obstetrics, Gynecology, and Reproductive
Sciences
Yale University School of Medicine
New Haven, Connecticut

Shabnam Peyvandi, MD

Assistant Professor of Pediatrics
Department of Pediatric Cardiology
University of California, San Francisco
Benioff Children's Hospital
San Francisco, California

Cate Pihoker, MD

Professor of Pediatrics
Department of Endocrinology and Diabetes
University of Washington
Seattle Children's Hospital
Seattle, Washington

Erin Plosa, MD

Assistant Professor of Pediatrics
Department of Pediatrics
Vanderbilt University
Nashville, Tennessee

Brenda B. Poindexter, MD, MS

Associate Professor of Pediatrics
Section of Neonatal-Perinatal Medicine
Indiana University School of Medicine
Indianapolis, Indiana

Michael A. Posencheg, MD

Medical Director
Intensive Care Nursery
Neonatology and Newborn Services
Hospital of the University of Pennsylvania
Associate Professor of Clinical Pediatrics
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania

Benjamin E. Reinking, BA, MD

Clinical Professor of Pediatrics
Stead Family
Department of Pediatrics
University of Iowa Carver College of Medicine
Iowa City, Iowa

Samuel Rice-Townsend, MD

Attending Surgeon
Department of Surgery
Boston Children's Hospital
Assistant Professor
Harvard Medical School
Boston, Massachusetts

Morgan K. Richards, MD, MPH

Resident
Department of Surgery
University of Washington
Seattle, Washington

C. Peter Richardson, PhD

Associate Research Professor
Department of Pediatrics
University of Washington
Department of Pulmonary and Newborn Care
Seattle Children's Hospital
Principal Investigator
Center for Developmental Therapy
Seattle Children's Research Institute
Seattle, Washington

Kelsey Richardson, MD

Pediatric Nephrology Fellow
Department of Nephrology

Preface

“The neonatal period ... represents the last frontier of medicine, territory which has just begun to be cleared of its forests and underbrush in preparation for its eagerly anticipated crops of saved lives.” Introduction to the first edition of Schaffer’s Diseases of the Newborn

History

The first edition of *Diseases of the Newborn* was published in 1960 by Dr. Alexander J. Schaffer, a well-known Baltimore pediatrician who coined the term *neonatology* to describe this emerging pediatric subspecialty that concentrated on “the art and science of diagnosis and treatment of disorders of the newborn infant.” Schaffer’s first edition was used mainly for diagnosis, but also included descriptions of new neonatal care practices (i.e., the use of antibiotics, temperature regulation, and attention to feeding techniques)—practices that had led to a remarkable decrease in the infant mortality rate in the United States, from 47 deaths per 1000 live births in 1940 to 26 per 1000 in 1960. But a pivotal year for the fledgling subspecialty of neonatology came 3 years later in 1963, with the birth of President John F. Kennedy’s son, Patrick Bouvier Kennedy, at 35 weeks’ gestation (i.e., late preterm). His death at 3 days of age, from complications of hyaline membrane disease, accelerated the development of infant ventilators that, coupled with micro-blood gas analysis and expertise in the use of umbilical artery catheterization, led to the development of intensive care for newborns in the 1960s on both sides of the Atlantic. Advances in neonatal surgery and cardiology, along with further technological innovations, stimulated the development of neonatal intensive care units and regionalization of care for sick newborn infants over the next several decades. These developments were accompanied by an explosion of neonatal research activity that led to improved understanding of the pathophysiology and genetic basis of diseases of the newborn, which in turn has led to spectacular advances in neonatal diagnosis and therapeutics—particularly in the care of preterm infants. Combined, these efforts led to continued improvements in the infant mortality rate in the United States, from 26 deaths per 1000 live births in 1960 to 5.8 deaths per 1000 live births in 2014. Current research efforts are focused on decreasing the striking regional, ethnic, and global disparities in infant mortality rates, improving neonatal outcomes, advancing neonatal therapeutics, preventing newborn diseases, and finally—teaming with our obstetrical colleagues—preventing prematurity. We neonatologists would like to begin downsizing, instead of continually expanding, our neonatal intensive care units!

Dr. Mary Ellen Avery joined Dr. Schaffer for the third edition of *Diseases of the Newborn* in 1971. For the fourth edition in 1977, Drs. Avery and Schaffer recognized that their book now needed multiple contributors with subspecialty expertise and they became co-editors, rather than sole co-authors, of the book. In the preface

to that fourth edition, Dr. Schaffer wrote, “We have also seen the application of some fundamental advances in molecular biology to the management of our fetal and newborn patients”—referring to the new knowledge of hemoglobinopathies. Dr. Schaffer died in 1981 and Dr. H. William Taeusch joined Dr. Avery as co-editor for the fifth edition in 1984. Dr. Roberta Ballard joined Drs. Taeusch and Avery for the sixth edition in 1991, with the addition of Dr. Christine Gleason for the eighth edition in 2004. Drs. Avery, Taeusch, and Ballard retired from editing the book in 2009, and became “editors emeriti.” Dr. Sherin Devaskar joined Dr. Gleason as co-editor for the ninth edition, bringing a wonderfully fresh perspective, as well as new contributors to the book. For this, the tenth edition, Dr. Sandra “Sunny” Juul teamed with Dr. Gleason as co-editor—the first time that co-editors have been faculty at the same institution since the fifth edition was published in 1984.

What’s New and Improved About This Edition?

We are thrilled that the book is now in full color—no need to flip back and forth from the chapter text to the color plates at the front of the book! Also new to this edition are several Key Points that contributors have added to the beginning of each chapter, providing readers with a quick summary of the most important content. The Expert Consult eBook version includes new features, such as ultrasound videos, and has been enhanced to make content more easily searchable, shareable (via a new Social Media feature), portable, and perpetual.

The book continues to be thoroughly (and sometimes painfully) revised and updated by some of the best clinicians and investigators in their field—several of whom are new contributors to this edition. Some chapters required more extensive revision than others, particularly those that deal with areas in which we have benefitted from new knowledge and/or its application to new diagnostic and therapeutic practices. This is particularly true in areas such as neurology, hematology, global health and neonatal screening, and genomics. Several new chapters have been added that reflect the continued growth and development of our subspecialty. These include chapters on brain injury (both preterm and term), palliative care, gastroesophageal reflux, platelet disorders, transfusion therapy, neonatal hypertension, and the ear/hearing disorders.

With the incredible breadth and depth of information immediately available to neonatal caregivers and educators on multiple online sites, what’s the value of a printed textbook? We, the co-editors of this tenth edition, believe that textbooks such as *Diseases of the Newborn* and all forms of integrative scholarship, will always be needed—by clinicians striving to provide state-of-the-art neonatal care, by educators striving to train the next generation of caregivers, and by investigators striving to advance neonatal research and

scholarship. A textbook's content is only as good as its contributors and this textbook, like the previous editions, has awesome contributors. They were chosen for their expertise and ability to integrate their knowledge into a comprehensive, readable, and useful chapter. They did this despite the demands of their day jobs in the hopes that their syntheses could, as Ethel Dunham wrote in the foreword to the first edition, "spread more widely what is already known ... and make it possible to apply these facts."

Although the online versions of this and other textbooks enjoy increasingly popular use, in 2017—a full 57 years after the publication of the first edition of this book—we still find copies of this and other textbooks important to our subspecialty lying dog-eared, coffee-stained, annotated, and broken-spined in places where neonatal caregivers congregate. These places, these congregations of neonatal caregivers, are now present in nearly every country around the world. The tentacles of neonatal practice and education are spreading—ever deeper, ever wider—to improve the outcome of pregnancy worldwide. Textbooks connect us to the past, bring us up to date with the present, and prepare and excite us for the future. We will always need them, in one form or another, at our sites of practice. To that end, we have challenged ourselves to meet, and hopefully exceed, that need—for our field, for our colleagues, and for the babies.

Acknowledgments and Gratitude

We wish to thank key staff at Elsevier—Dee Simpson, senior developmental editor, Kate Dimock, our original publishing director, Sarah Barth, our new senior content strategist, and Sharon Corell, senior project manager. Each demonstrated patience, guidance, and persistence; without them, we would still be hard at work, trying to make this book a reality! We also wish to thank our staff and colleagues at our academic institution, the University of Washington, especially our Department Chair, F. Bruder Stapleton, whose leadership and unwavering support have meant a great deal to us both. We are indebted to our contributors, who actually *wrote* the book and did so willingly, enthusiastically, and (for the most part) in a timely fashion—despite myriad other responsibilities in their lives. Finally, we are deeply grateful for the support of our families throughout the long, and often challenging, editorial process.

Christine Gleason and Sandra Juul

Neonatal and Perinatal Epidemiology

NIGEL PANETH AND TRACY THOMPSON

KEY POINTS

- Population-level study of pregnancy and infancy has been an important component of the success of newborn care.
- Disease, mortality, and later outcomes patterns are complex. Some factors (i.e., preterm birth and birthweight) are stable, while others (i.e., cesarean section and twinning rates) can undergo rapid change.
- The success of newborn intensive care is well established and has substantially lowered mortality rates in a short period of time primarily because of the evidence-based nature of neonatal practice.
- Survivors of neonatal intensive care face educational and rehabilitative needs. Recent interventions have reduced the burden of brain damage.
- Sudden infant death syndrome (SIDS), through careful epidemiologic study and active discouragement of prone sleeping, has been reduced by 70% in the United States.
- Observational research and randomized trials have led to increased folate intake and a substantial reduction in neural tube birth defects.

The period surrounding the time of birth, the *perinatal* period, is a critical episode in human development, rivaling only the period surrounding conception in its significance. This time period is when the infant makes the critical transition from its dependence upon maternal and placental support (oxidative, nutritional, and endocrinologic) and establishes independent life. That this transition is not always successful is signaled by a mortality risk in the neonatal period that is not exceeded until age 75–84 and risks for damage to organ systems, most notably the brain, that can be lifelong (Murphy et al., 2013). The developing human organism often does not manifest the immediate effects of even profound insults. Years must pass before the damage to higher cortical functions of insults and injuries occurring during the perinatal period can be reliably detected. Epidemiologic approaches to the perinatal period must therefore be bidirectional: looking backwards from birth to examine the underlying causes of adverse health conditions that arise or complicate the perinatal period and looking forward to later life to see how these conditions shape disorders of health in childhood and adulthood.

Health Disorders of Pregnancy and the Perinatal Period

Key Population Mortality Rates

Maternal and child health in the population has traditionally been assessed by monitoring the two key rates of maternal mortality and infant mortality (IM). Maternal mortality is defined by the World Health Organization (WHO) as the death of a woman during pregnancy or within 42 days of pregnancy, denominated either to live births or to all births (this must be specified) in the population being studied (WHO, 2010). Because pregnancy can contribute to deaths beyond 42 days, some have argued for examining all deaths within a year of a pregnancy but later deaths are not included in standard tabulations of maternal mortality (Hoyert, 2007). When the cause of death is attributed to a pregnancy-related condition, it is described as *direct*. When pregnancy has aggravated an underlying health disorder present before pregnancy, the death is termed an *indirect* maternal death. The WHO recommends that both direct and total (direct plus indirect) maternal mortality rates be provided.

Deaths unrelated to pregnancy, but taking place in women within 42 days of pregnancy, are termed *incidental* maternal deaths and are not included in maternal mortality (Khlal, 2006). But even incidental deaths may bear a relation to pregnancy; homicide and suicide, for example, are more common during pregnancy and shortly thereafter and might not be entirely incidental to it (Shadigian and Bauer, 2005; Samandari et al., 2010).

In most geographic entities, IM is defined as all deaths occurring from birth to 365 days of age in a calendar year divided by all live births in the same year. This approach makes for imprecision, as some deaths in the examined year occurred in the previous year's birth cohort, and some births in the examined year will die as infants in the following year. In recent years, birth–death linkage has permitted vital registration areas in the United States to provide IM rates that avoid this imprecision. The standard IM rate reported by the National Center for Health Statistics (NCHS) links *deaths* for the index year to all births, including those taking place the *previous* year. This form of IM is termed *period* IM. An alternative procedure is to take births for the index year and link them to

infant deaths, including those taking place the *following* year. This is referred to as *birth cohort* IM and is not used for regular annual comparisons because it cannot be completed in as timely a fashion as period IM (Mathews, 2015).

Infant deaths are often divided into deaths in the first 28 days of life (*neonatal* deaths) and deaths later in the first year (*postneonatal* deaths). Neonatal deaths, which are largely related to preterm birth and birth defects, tend to reflect the circumstances of pregnancy whereas postneonatal deaths, when high, are nearly all from infection, often in the setting of poor nutrition. Thus in underdeveloped countries, postneonatal deaths dominate; in industrialized countries, the reverse is true. In the United States, neonatal deaths have been more frequent than postneonatal deaths since 1921. In recent years, the ratio of neonatal to postneonatal deaths in the United States has consistently been about 2:1.

Perinatal mortality is a term used for a rate that combines stillbirths and neonatal deaths in some fashion (Box 1.1) Stillbirth reporting prior to 28 weeks, even in the United States, where such stillbirths are required to be reported in every state, is probably incomplete. Nonetheless, stillbirths continue to be reported at a level not much lower than that of neonatal deaths, and our understanding of the causes of stillbirth remains very uncertain (Paneth, 2012; Lawn et al., 2016).

Sources of Information on Mortality–Vital Data

All US mortality data depend upon the collection of information about all births and deaths. Routinely collected vital data are the

• BOX 1.1 Glossary of Terms

Preterm birth – less than 37 weeks' gestation

- **Very preterm** – less than 32 weeks' gestation
- **Extremely preterm** – less than 28 weeks' gestation

Low birth weight – infant weighs less than 2500 g (5 lb 8 oz) at birth regardless of gestational age

- **Moderately low birth weight** – an infant weighing at least 1500 g but less than 2500 g at birth regardless of gestational age
- **Very low birth weight** – an infant weighing less than 1000 g (2 lb 3 oz) at birth regardless of gestational age

Maternal mortality ratio – death of a woman during pregnancy or within 42 days of pregnancy compared with either live births or with all births in the population

- **Direct maternal mortality** – a maternal death attributed to a pregnancy-related cause
- **Incidental maternal mortality** – a maternal death occurring during the defined time period for maternal mortality but unrelated to pregnancy
- **Indirect maternal mortality** – a maternal death caused by the pregnancy aggravating an underlying health disorder present before pregnancy

Infant mortality rate – all deaths occurring from birth to 365 days of age in a calendar year divided by all live births in the same year

Birth cohort infant mortality – births for the index year are linked to infant deaths including those taking place the following year

Neonatal mortality – infant deaths within the first 28 days of life

Perinatal mortality rate – number of stillbirths that occur after 22 weeks' gestation and deaths in the first week of life per 1000 total births

Period infant mortality – all infant deaths in a calendar year linked to births, including births that took place in the previous year

Postneonatal mortality – infant deaths after the first 28 days of life but before the 366th day of life

nation's key resource for monitoring progress in caring for mothers and children. Annual counts of births and deaths collected by the 52 vital registration areas of the United States (50 states, District of Columbia, and New York City) are assembled into national data sets by the NCHS. Unlike data collected in hospitals or clinics, or even from nationally representative surveys, birth and death certificates are required by law to be completed for each birth and death. Birth and death registration have been virtually 100% complete for all parts of the United States since the 1950s. The universality of this process renders many findings from vital data analyses stable and generalizable, although formatting changes in 2003, affecting both the death and birth certificates, have created some difficulties in interpretation.

For example, since 2003 the US Standard certificate of death, which is recommended for adoption by US vital registration areas, has included a special requirement for identifying whether the decedent, if female, was pregnant or had been pregnant in the previous 42 days. This simple check box on the death certificate has been shown to increase the number of deaths recognized as maternal in states that have followed the 2003 model and incorporated questions about pregnancy in their death certificates (Mac et al., 2011).

Fig. 1.1 illustrates the most recent (2003) nationally recommended standard for birth certificate data collection, which had been adopted for use by 33 states by 2010 (Curtin et al., 2013). The remaining states use birth certificates formatted according to the 1989 standard. While, as we discuss below, some items are collected differently on the two certificate templates, unlike maternal mortality, these changes do not affect the number of reported deaths.

The limitations of vital data are well known. Causes of death are subject to certifier variability and perhaps more importantly to professional trends in diagnostic categorization. The accuracy of recording of conditions and measures on birth certificates is often uncertain and variable from state to state and from hospital to hospital. Yet the frequencies of births and deaths in sub-groups defined objectively and recorded consistently, such as birthweight and mode of delivery, are likely to be valid.

Time Trends in Mortality Rates of the Perinatal Period in the United States

Maternal mortality and IM declined steadily through the 20th century. By 2000, neonatal mortality was 10% of its 1915 value, postneonatal mortality less than 7%, and maternal mortality less than 2%. The contribution to these changes of a variety of complex social factors, including improvements in income, housing, birth spacing, and nutrition, has been widely documented, as has the role of ecologic-level public health interventions that have produced cleaner food and water (Division of Reproductive Health, 1999). Public health action at the individual level, including targeted maternal and infant nutrition programs and immunization programs, has made a lesser but still notable contribution. Medical care per se was, until recently, less critically involved, with the exception of the decline in maternal mortality, which was very sensitive to the developments in blood banking and antibiotics that began in the 1930s. To this day hemorrhage and infection account for a large fraction of the world's maternal deaths (Khan et al., 2006).

A notable feature of the past half-century or so is the sharp decline in all three mortality rates beginning in the 1960s following a period of stagnation in the 1950s (Fig. 1.2) The decline began with maternal mortality, followed by postneonatal, and then

neonatal. The contribution of medical care of the neonate was most clearly seen in national statistics in the 1970s, a decade that witnessed a larger decline in neonatal mortality than in any previous decade of the century. All of the change in neonatal mortality between 1950 and 1975 was in mortality for a given birthweight; no improvement was seen in the birthweight distribution (Lee et al., 1980). This finding suggested that the effectiveness of newborn intensive care has had a striking impact on mortality in very small babies. Prior to the development of newborn intensive care, survival at birthweights less than 1000 g was very rare. In 2013, the US survival rate to 1 year for infants with a birthweight between 501 and 999 g was 75%, and the number of survivors at age 1 was over 16,000.

In retrospect, three factors seem to have played critical roles in the rapid development of the newborn intensive care programs that largely accounted for the rapid decline in birthweight-specific neonatal mortality that characterized national trends in the last third of the 20th century. The first was the willingness of medicine to provide more than nursing care to marginal populations such as the premature infant. While the death of the mildly premature son of President Kennedy in 1963 provided a stimulus to the development of newborn intensive care, it should be noted that the decline in IM that began in the 1970s was paralleled by a similar decline in mortality for the extremely old (Rosenwaik et al., 1980). This was, perhaps, an indicator that the availability of federal funding through Medicare and Medicaid enabled previously underserved populations at the extremes of age to receive greater medical attention than they had before. The Medicaid program, adopted in 1965, may have made it feasible for the first time to pay for the intensive care of premature newborns, among whom the medically indigent are over-represented. While financial support for newborn intensive care may have been a necessary ingredient in its development, finances would have not been sufficient to improve neonatal mortality had not new medical technologies, especially those supporting ventilation of the immature newborn lung, been developed at about the same time (Gregory et al., 1975).

Advances in newborn care have ameliorated the impact of premature birth and birth defects on mortality. Unfortunately, the underlying disorders that drive perinatal mortality and the long-term developmental disorders that are sometimes their sequelae have shown no tendency to abate. With the very important exception of neural tube defects, whose prevalence has declined with folate fortification of flour in the United States and programs to encourage intake of folate in women of child-bearing age (Mathews et al., 2002), the major causes of death (preterm birth and birth defects) have not declined, nor has cerebral palsy, the major neurodevelopmental disorder that can be of perinatal origin (Paneth et al., 2006). Progress has come from improved medical care of the high-risk pregnancy and the sick infant, rather than through understanding and prevention of the disorders themselves.

The pace of decline in infant, neonatal, and postneonatal mortality in the United States began to slow in 1995 and changed little in the following decade. A modest decline was seen, however, between 2005 and 2010 (Table 1.1). Data from the Vermont Oxford Neonatal Network encompassing more than a quarter of a million newborns from hundreds of largely North American neonatal units showed a decline in mortality of 12.2% for infants of 501–1500 g for 1990–1999 (Horbar et al., 2002) and a further 13.3% decline for 2000–2009 (Horbar et al., 2012). These declines are more modest than in the early days of newborn intensive care. From 1960–1985, a greater than 50% decline in mortality for

infants of 501–1500 g was recorded in national data (Buehler et al., 1987; Prager, 1994), even though much of the first decade of that interval preceded the use of newborn intensive care technology in all but a few pioneering centers. The pace of advances in newborn medicine and the expansion of newborn intensive care to populations previously underserved, factors that have exerted a constant downward pressure on IM since the 1960s, have lessened in the past two decades or so.

Reported maternal mortality has actually climbed substantially in recent years, but this is almost certainly the effect of the improved reporting described above. The Centers for Disease Control (CDC) has a special unit dedicated to the problem of maternal mortality, the Pregnancy Mortality Surveillance System (CDC, 2017). Established in 1987, its counts of maternal deaths, based on more in-depth exploration than is possible from a vital registration system alone, have provided consistently higher estimates of maternal

mortality than data reported by the NCHS, as shown in Fig. 1.2. Recognizing this, and the variation in reporting resulting from the variable use by states of the 2003 recommendation for identifying recent pregnancies on death certificates, the NCHS stopped reporting maternal mortality in 2008 (Minino et al., 2011). All recent maternal mortality data in the US are produced by the Pregnancy Mortality Surveillance System.

The risk of preterm birth (<37 weeks' gestation) increased steadily in the first years of the present century, peaked in 2007, and has declined by 8% since (Hamilton et al., 2015). The increase was largely in moderately preterm babies and likely reflected an increased willingness on the part of obstetricians to deliver fetuses earlier in gestation who were not doing well in utero, as well as the increased prevalence of twins and triplets, who are generally born preterm, resulting from in vitro fertilization. The newer data suggest a reversal of these earlier practices.

The recording of diabetes in pregnancy more than doubled from 1995 to 2010, but the NCHS has suggested that some of this might reflect more complete reporting on the 2003 birth certificate revision (Martin et al., 2010b). The differences in the two forms of birth certificate in circulation, and the uneven implementation of the newer version in vital registration areas, led NCHS, in 2008 (Martin et al., 2010a), to omit regular reporting of smoking, alcohol intake, weight gain, late prenatal care, and pregnancy-associated hypertension, among other variables, from its regular tabulations in annual natality reports, and these are not provided for 2010 in Table 1.1.

The cesarean section rate continues its long-term increase, from 5% in 1970 to 23% in 1990, peaking at nearly 33% in 2010, with a faint decline since (Hamilton et al., 2015). The reasons for this increase are multifactorial and include pressures from patients, physicians, and the medical malpractice system. The steady reduction in smoking in pregnancy is likely to be real, whereas trends in the self-reporting of alcohol use in pregnancy may be influenced by societal norms and expectations. Fewer women seem to have late or no prenatal care in recent years, but perhaps surprisingly, more women are found to have inadequate pregnancy weight gain at term. A very slight uptick in the fertility rate follows a long-term (since about 1960) decline in fertility in the United States. More than 4 in 10 mothers in the United States are now unmarried when they give birth.

International Comparisons

The US lag in IM, in comparison to other developed nations, is well known; the United States ranked 26th in IM among the Organization for Economic Co-operation and Development countries in 2010 (MacDorman et al., 2014). This surprising phenomenon, in light of more favorable socioeconomic and medical care circumstances in the United States than in many nations with lower IM, cannot be attributed to inferior neonatal care. Mortality rates for low birth weight infants are generally lower in the United States than in European and Asian nations, though mortality at term may be slightly higher. The key difference, however, is that the United States suffers from a striking excess of premature births. While the US African-American (AA) population is especially vulnerable to prematurity, and especially severe prematurity, prematurity rates are also considerably higher in white Americans than in most European populations. It is likely that the recording of marginally viable small infants as live births rather than stillbirths is more pronounced in the United States than in Europe (Kramer et al., 2002). While this practice does make a

contribution to our higher prematurity and IM rates, it cannot fully explain them.

Premature birth, fetal growth retardation, and IM are tightly linked, in every setting in which they have been studied, to most measures of social class, especially to maternal education. However, uncovering precisely what it is about lower social class that drives these important biologic differences has been elusive. Factors such as smoking have at times been implicated but can only explain a small fraction of the social class effect. It is unlikely that this situation will change until a better understanding of the complex social, environmental, and biologic roots of preterm birth are achieved.

Health Disparities in the Perinatal Period

In 2010, 54.1% of all US births were to non-Hispanic white mothers; 23.6% were to Hispanic mothers; 14.7% were to AA mothers; and the remainder were to mothers of other ethnic groups (Table 1.2). Health disparities are especially prominent in the perinatal period, with AA infant IM stubbornly remaining about double that of white IM in the United States, even as rates decline in both populations. Preterm birth is the central contributor to this racial disparity in IM, and the more severe the degree of prematurity, the higher the excess risk for AA infants. The risk of birth before 37 weeks of gestation was 1.5 times higher in AA mothers than among non-Hispanic whites in 2010, but the risk of birth before 32 weeks was twice as high. Reduction in IM disparities in the United States thus requires better understanding of the etiology and mechanisms of preterm birth. Birth defect mortality shows a less pronounced gradient by ethnic group and does not contribute in a major way to overall IM disparities (Yang et al., 2006).

The *Hispanic paradox* is a term often used to describe the observation that IM is the same or lower in US citizens classified as Hispanic than in non-Hispanic whites, in spite of the generally lower income and education levels of US Hispanics (Hessol and Fuentes-Afflick, 2005). The IM experience of Hispanics in the United States reflects the principle that premature birth and low birth weight are key determinants of IM, as these parameters are also favorable in Hispanics. Smoking is much less common among Hispanics in the United States, but this factor alone does not fully explain the paradox.

Major Causes of Death

Cause-of-death analysis, a staple of epidemiologic investigation, has limitations when applied to the perinatal period. Birth defect mortality is probably reasonably accurate, but causes of deaths among prematures are divided among categories such as respiratory distress syndrome, immaturity, and a variety of complications of prematurity. Choice of which particular epiphenomenon of preterm birth should be chosen to be listed as the primary cause of death is to some extent arbitrary. Some maternal complications, such as preeclampsia, are also occasionally listed as causes of newborn death, and birth defects and preterm birth often overlap. However categorized, prematurity per se accounts for at least a third of infant deaths (Callaghan et al., 2006).

In the period before prenatal ultrasound permitted reasonably accurate gestational age estimation, a high fraction of neonatal deaths were attributed to low birth weight, but most of these deaths occurred in premature infants, because premature birth is much more important as a cause of death than is fetal growth restriction. Extreme prematurity makes a contribution to IM well

beyond its frequency in the population. The 1.9% of births born prior to 32 weeks in 2010 contributed 53% of all infant deaths.

After premature birth, the next most important group of causes of death is congenital anomalies. With the signal exception of the folate–neural tube association, we have no clearly effective primary prevention program for any birth defect. Pregnancy screening and termination of very severe defects are, however, an option for many mothers and there is evidence that this practice does contribute to a reduced prevalence of chromosomal anomalies at birth (Loane et al., 2013).

The major postneonatal cause of death since about the 1970s in the United States is the sudden infant death syndrome (SIDS). This cause of death has declined substantially in the United States in parallel with successful public health efforts to discourage prone sleeping in infancy (Mitchell, 2009).

Major Morbidities Related to the Perinatal Period

The principal complications of preterm birth involve five organs – lung, heart, gut, eye, and brain. Management of respiratory distress syndrome and its short-term and longer-term complications is the centerpiece of neonatal medicine. Surgical or medical management of symptomatic patent ductus arteriosus is the major cardiac challenge for the premature, and we have yet to understand the quite striking variations, by time and place, of necrotizing enterocolitis, a disorder that in its most extreme forms can cause death or substantial loss of bowel function. Retinopathy of prematurity (ROP) is closely related to arterial oxygen levels, and the epidemic levels of this disorder encountered in the 1950s, when oxygen was freely administered without monitoring, was a major setback for

neonatal medicine (Silverman, 1980). However, even with much more careful management of oxygen, ROP continues to occur.

The largest unsolved problem in neonatal medicine remains the high frequency of brain damage in premature survivors. The extraordinary decline in mortality rates has not been paralleled by similar declines in rates of neurodevelopmental disabilities in survivors. Indeed, the key epidemiologic feature of cerebral palsy rates in population registries toward the end of the 20th century was a modest overall increase in the prevalence of that disorder attributable entirely to the increasing number of survivors of very low birth weight. There are suggestions that this rise has leveled off since the 1990s (Smithers-Sheedy et al., 2016).

Factors Affecting Perinatal Health

Health States in Pregnancy

The major causes of neonatal morbidity (prematurity and birth defects) generally occur in pregnancies free of antecedent complications. Having a previous birth with an anomaly or a previous preterm birth both raise the maternal risk for recurrence of the condition. Indeed, for preterm birth, no other known risk factor carries as much risk as having previously delivered preterm.

More than a quarter of preterm birth is iatrogenic, the result of induced labor in pregnancies in which the fetus is severely compromised (Morken et al., 2008). Generally the reason is preeclampsia with attendant impairments in uterine blood flow and poor fetal growth, but poor uterine blood flow and impaired fetal growth can also occur independently of diagnosed preeclampsia. The other major complication of pregnancy is diabetes, most often gestational but at times preexisting. Insulin resistance in the mother promotes the movement of nutrients toward the fetus, and typically the infant of the diabetic mother is large for gestational age. Severe diabetes, however, can be accompanied by fetal growth retardation.

Health Behaviors

The most carefully studied and well-established health behavior affecting newborns is maternal cigarette smoking, which more than doubles the prevalence of babies with intrauterine growth retardation and increases the risk of premature birth by 20%–50% (Dietz et al., 2010). Infants growth retarded from smoking paradoxically survive slightly better than do infants of the same weight whose mothers did not smoke, but the net effect of smoking, which also shortens gestation slightly, is to increase perinatal mortality. The risk of SIDS is also increased in the babies of smoking mothers (Mitchell and Milerad, 2006). Although the subject is much debated, it has not been conclusively shown that prenatal smoking has independent long-term effects on child cognitive capacity (Breslau et al., 2005).

Mothers who drink alcohol heavily in pregnancy are at risk of having infants with the cluster of defects known as the fetal alcohol syndrome (Jones et al., 2013). Cocaine use in pregnancy is a severe growth retardant (Janisse et al., 2014) and may affect neonatal behavior, but the long-term effects of this exposure on infant cognition and behavior are not as great as initially feared (Bandstra et al., 2010).

Perinatal Medical Care

In light of the potent effects of medical care on the neonate, it has been important to develop systems of care that ensure, or at

least facilitate, provision of care to neonates in need. This concept was first promoted by the March of Dimes Foundation, which in its committee report of 1976 recommended that all hospitals caring for babies be classified as either Level 1 (care for healthy and mildly ill newborns), Level 2 (care for most sick born-in newborns but not accepting transfers), and Level 3 (regional centers caring for complex surgical disease and receiving transfers) (Health, 1976). This concept of a regional approach to neonatal care, with different hospitals playing distinct roles in providing care, was endorsed by organizations such as the American College of Obstetricians and Gynecologists, the American Academy of Pediatrics, and by many state health departments. While it is important to transfer sick babies to Level 3 centers when needed, it is preferable, if at all possible, to transfer mothers at risk of delivering prematurely or of having a sick neonate, because transport of the fetus in utero is far superior to any form of postnatal transport. Birth at a Level 3 center has consistently been shown to produce lower mortality rates in low birth weight infants than birth in other levels of care (Lasswell et al., 2010).

Epidemiologic Study Designs in the Perinatal Period

Epidemiologic studies have contributed substantially to better understanding of patterns of risk and prognosis in the perinatal period, to tracking patterns of mortality and morbidity, to assessment of regional medical care, and to assisting physicians and other providers to evaluate the efficacy of treatments. The use of vital data to provide a picture of the overall health of mothers and infants and to monitor important time trends has already been mentioned, but cohort studies and randomized controlled trials have been essential to advances in neonatology.

Cohort Studies in Pregnancy/Birth

Studies that follow populations of infants over time, beginning at birth or even before birth, continuing to hospital discharge, to early childhood, or even into adult life, are the leading sources of information about perinatal risk factors for disease and adverse outcomes. As with all observational studies, cohort studies produce associations of exposures and outcomes whose strength and consistency must be carefully judged in the light of other biologic evidence and with attention to confounding and bias. Collaborations across centers in assembling such data are very valuable. One such notable collaboration is the Vermont–Oxford Network, which provides continuous information on the frequency of conditions observed and diagnoses made in hundreds of US overseas hospitals, with a particular emphasis on using these data for improving care (Horbar et al., 2010). The National Institute of Child Health and Human Development (NICHD)-supported neonatal network has not only been a rich source of randomized trials but also has produced observations about prognosis based on very large samples of low birth weight babies (Stoll et al., 2015). The above collaborations focus mainly on the period until hospital discharge.

Multicenter cohort studies focusing on diagnosis and follow-up of brain injury in prematures, such as the Developmental Epidemiology Network Study (DEN) (Kuban et al., 1999), Neonatal Brain Hemorrhage Study (NBH) (Pinto-Martin et al., 1992), and Extremely Low Gestational Age Newborn Study (ELGAN) (O'Shea et al., 2009), have contributed much to our understanding of the

prognostic value of brain injury imaged by ultrasound in the neonatal period because they include follow-up to age 2 or later. Of particular value have been regional or population-wide studies of low birth weight infants with follow-up to at least school age, among which are included the NBH study from the United States and also important studies from Germany (Breeman et al., 2015; Bruin et al., 2015), Great Britain (Petrou et al., 2013), and Canada (Van Lieshout et al., 2015).

Newborn intensive care has been in place long enough that the first reports of adult outcomes in very small infants are now emerging (Saigal and Doyle, 2008). These studies paint a picture that is perhaps less dire than many had anticipated.

From 1959 to 1966, the National Collaborative Perinatal Project assembled data on approximately 50,000 pregnancies in 12 major medical centers and followed them to age 7 (Niswander, 1972). This highly productive exercise, one of whose major contributions was to show that birth asphyxia is a rare cause of cerebral palsy, has now been followed by the development of even larger pregnancy cohort studies. These studies, all of which archive biologic material such as blood and/or urine in pregnancy, should, in principle, permit us to learn a great deal about the unrecognized pregnancy factors that lead to adverse perinatal and child health outcomes. For reasons not entirely clear, a sample size of 100,000 has been universally adopted in studies in Norway (Magnus et al., 2006), Denmark (Olsen et al., 2001), and most recently Japan (Nitta, 2016). Efforts to mount a similar study in the United States were, unfortunately, not successful (Duncan et al., 2015).

Randomized Controlled Trials

Few areas of medicine have adopted the randomized trial as wholeheartedly as newborn medicine. The number of trials mounted has been large and their influence on practice strong. A notable influence on this field has been the National Perinatal Epidemiology Unit (NPEU) at Oxford University, established in 1978, which prioritized randomized trials among their several investigations of perinatal care practices and other circumstances affecting maternal and newborn outcomes. The NICHD neonatal research network was established in 1986, principally to support trials in *newborns*. Hundreds of trials have been mounted by just these two

organizations alone, but many other centers have contributed to the trial literature.

Trials in *pregnancy or in labor* have also been supported by the NPEU and by a network of obstetric centers supported by NICHD, the maternal-fetal network. These trials have often had important implications for newborns as well as for mothers; most notably, the one trial that has thus far successfully reduced the risk of preterm birth is the administration of 17 alpha-hydroxyprogesterone caproate in mid-gestation to high-risk women (Meis et al., 2003). Vaginal progesterone may also be effective (O'Brien and Lewis, 2016).

Most newborn trials have focused on outcomes evident in the newborn period, such as mortality, chronic lung disease, brain damage visualized on ultrasound, duration of mechanical ventilation, and/or hospital stay. Recently, however, trials extending into infancy or even to early childhood that incorporate measures of cognition or neurologic function have been a welcome addition to the trial arena. In the past few years we have learned from such trials that moderate hypothermia can reduce mortality and disability in asphyxiated term infants (Shankaran et al., 2005), caffeine treatment for apnea may reduce cerebral palsy (Schmidt et al., 2007), and magnesium sulfate administered in labor may reduce the risk of cerebral palsy (Rouse et al., 2008).

Trials in which both mortality and later outcome are combined raise complex methodologic issues. Imbalance in the frequency of the two outcomes being combined can result in random variation in the commoner outcome overwhelming a significant finding in the other. Providing the same weight in a trial to a disability and to a death raises ethical questions. Precisely how best to conduct such dual or multi-outcome trials is the subject of discussion and debate in the neonatal and epidemiologic communities.

As trials multiply, not all of them sufficiently powered, the methodology for summarizing them and drawing effective conclusions has become increasingly important to neonatologists. The terms *systematic review* and *metaanalysis* have firmly entered the research lexicon, especially the randomized trial literature. The Cochrane collaboration is an international organization that uses an army of volunteers to systematically review trial results in all fields of medicine. The collaboration, established in 1993, began in the field of perinatal medical trials. Systematic reviews of neonatal trials reviewed by the Cochrane Collaboration are hosted on the website of NICHD <https://www.nichd.nih.gov/cochrane>.

Summary and Conclusions

The patterns of disease, mortality, and later outcome in the perinatal period are complex. Some factors, such as the long-term trends in preterm birth and birthweight, are reasonably stable, while others, such as the rates of cesarean section and twinning, can undergo rapid change. The success of newborn intensive care is well established. No other organized medical care program, targeted at a broad patient population, has had such remarkable success in lowering mortality rates in such a short period of time. Much of that success is owed to the evidence-based nature of neonatal practice.

Nonetheless, this success has opened the door to new problems as survivors of intensive care face the challenges of the information age. Resource allocations similar to those that permitted the development of newborn intensive care are now needed to address the educational and rehabilitative needs of survivors. A hopeful sign is the success of some recently studied interventions in reducing the burden of brain damage.

On the nontechnologic front, targeted epidemiologic efforts to address perinatal disorders have yielded progress as well. Careful study of the circumstances surrounding infant sleep patterns led to active discouragement of prone sleeping, which has produced a halving of mortality from SIDS. Observational research, followed by two important randomized trials in Europe, led to interventions that increased folate intake in women of child-bearing age and a substantial reduction in the birth prevalence of neural tube defects.

The population-level study of health events occurring in pregnancy and infancy, their antecedents, and long-term consequences have been an important component of the success of newborn care. Careful self-evaluation through monitoring of vital data and of collaborative clinical data, rigorous assessment of new treatments through randomized trials, and alertness to opportunities to implement prevention activities following discovery of important risk factors should continue to guide care of the newborn.

Biomedical Informatics in Neonatology

JONATHAN P. PALMA AND PETER TARCZY-HORNOCH

KEY POINTS

- Although health care remains a quintessentially human endeavor, computers are playing a growing role in information management, particularly in neonatology.
- *Biomedical informatics* can be defined as “the interdisciplinary field that studies and pursues the effective uses of biomedical data, information, and knowledge for scientific inquiry, problem solving, and decision making, driven by efforts to improve human health” (Shortliffe and Blois, 2014).
- The trend in electronic health record (EHR) adoption is moving away from niche systems specific to neonatology and toward enterprise-wide systems, highlighting the importance of neonatologist involvement in the selection, implementation, and optimization of EHRs, which are not configured out of the box for the care of critically ill neonates.
- In evaluating therapeutic recommendations, at least 50% of studied treatments are of uncertain benefit. This gap is an opportunity for both evidence-based medicine (clinical trials) and exploration of “practice-based evidence” generated from EHRs.

Background

At a fundamental level, the practice of neonatology can be considered an information management problem. The care provider is combining patient-specific information (history, physical examination findings, and results of physiologic monitoring, laboratory tests, radiologic evaluation) with generalized information (medical knowledge, practice guidelines, clinical trials, personal experience) to make medical decisions (diagnostic, therapeutic, and management). The Internet has made possible a revolution in the sharing and disseminating of knowledge in all fields, including medicine, with continued growth and maturation of online clinical information resources and tools.

Although medicine remains a quintessentially human endeavor, computers play a vital role in information management, particularly in neonatology. Patient-specific and generalized information (medical knowledge) are increasingly available in electronic form. In the United States, a majority of hospitals have implemented electronic health record (EHR; also known as an *electronic medical record*) systems to manage patient-specific information, with levels of EHR adoption ranging from nursing documentation on electronic flow sheets (93.7%) to entirely paperless hospitals (at least 4.2%) (Healthcare Information and Management Systems Society, 2016) (Table 2.1). The American Recovery and Reinvestment Act of

2009 (ARRA; i.e., the federal economic stimulus plan) included the Health Information Technology for Economic and Clinical Health (HITECH) act, a provision for the investment of \$19 billion in health information technology to motivate physicians to adopt EHRs and \$1.1 billion to research the effectiveness of certain healthcare treatments. These ARRA provisions were predicated on the belief that quality, safety, and efficiency of clinical care can be improved through electronic medical records and evidence-based practice, a notion emphasized in the Institute of Medicine (IOM) reports *To Err is Human* (2000), which suggested that up to 98,000 patients die annually as a result of preventable medical errors, and *Crossing the Quality Chasm* (IOM, 2001), which identified health information technology as one approach to mitigating these errors.

To encourage substantive EHR implementation, the Centers for Medicare and Medicaid Services (CMS) established [Meaningful Use](#) objectives necessary to qualify for federal incentive payments. In 2011, Stage 1 of Meaningful Use encouraged the implementation of basic EHR systems; in 2014, Stage 2 was designed to promote more advanced EHR functionality; in 2018, Stage 3 objectives, which focus on improving quality, safety, and efficiency to achieve improved health outcomes, will be required in order to avoid penalties (<https://www.healthit.gov/providers-professionals/how-attain-meaningful-use>). Due to challenges in meeting objectives without undue burden on providers, the requirements for each stage continue to evolve. Recently, CMS leadership suggested major changes to Stage 3, adding flexibility and shifting the focus from use of technology to achievement of health outcomes.

Parallel with and related to the adoption of information technology is the growth of societal pressures to improve the quality of medical care while controlling costs. These pressures are beginning to affect the way in which medicine and neonatology are practiced. In turn, it is becoming important for neonatologists to understand basic principles related to biomedical and health informatics, databases, electronic medical record systems, and evaluation of therapeutic recommendations.

This expansion of information technology in clinical practice and the concurrent growth of medical knowledge hold great promise but have potential pitfalls. One pitfall that must not be underestimated, and which is as great a danger today as when Blois (1984) first cautioned against it, is the unquestioning adoption of information technology:

And, since the thing that computers do is frequently done by them more rapidly than it is by brains, there has been an irresistible urge

TABLE 2.1 Healthcare Information and Management Systems Society EMR Adoption Model

| UNITED STATES EMR ADOPTION MODEL SM | | |
|---|---|--------------|
| Stage | Cumulative Capabilities | 2015 Final % |
| Stage 7 | Complete EMR; CCD transactions to share data; data warehousing; data continuity with ED, ambulatory, OP | 4.2 |
| Stage 6 | Physician documentation (structured templates), full CDSS (variance & compliance), full R-PACS | 27.1 |
| Stage 5 | Closed loop medication administration | 35.9 |
| Stage 4 | CPOE, clinical decision support (clinical protocols) | 10.1 |
| Stage 3 | Nursing/clinical documentation (flow sheets), CDSS (error checking), PACS available outside radiology | 16.4 |
| Stage 2 | CDR, controlled medical vocabulary, CDS, may have document imaging; HIE capable | 2.6 |
| Stage 1 | Ancillaries – lab, rad, pharmacy – all installed | 1.7 |
| Stage 0 | All three ancillaries not installed | 2.1 |
| n = 5460 | | |
| <small>CCD, continuity of care document; CDR, clinical data repository; CDS, clinical decision support; CDSS, clinical decision support systems; CPOE, computerized provider order entry; ED, emergency department; EMR, electronic medical record; HIE, health information exchange; OP, outpatient; PACS, picture archive and communication systems; R-PACS, Radiology picture archive and communication systems. Data from HIMSS Analytics™ Database © 2016.</small> | | |

to apply computers to medicine, but considerably less of an urge to attempt to understand where and how they can best be used.

Adoption and meaningful use of EHRs is not simply a technology challenge: it is a people and process challenge as well. The recently established Clinical Informatics medical subspecialty aims to train physicians in the skills required to address each of these challenges.

Another present and real challenge is information overload, both in terms of the exponentially increasing corpus of medical knowledge and the large amounts of data available within EHRs. As early as 1995, [Bero and Rennie](#) observed:

Although well over 1 million clinical trials have been conducted, hundreds of thousands remain unpublished or are hard to find and may be in various languages. In the unlikely event that the physician finds all the relevant trials of a treatment, these are rarely

accompanied by any comprehensive systematic review attempting to assess and make sense of the evidence.

The potential of just-in-time information at the point of care is thus particularly appealing, especially considering that the growth in published literature continues at an accelerating rate, with a flood of new knowledge coming from the latest research in genomics, proteomics, metabolomics, and systems biology. In addition, the adoption of EHRs has resulted in the collection of large amounts of clinical data as a byproduct of routine care. A vision to address this was articulated by one of the editors of the *British Medical Journal*: “New information tools are needed: they are likely to be electronic, portable, fast, easy to use, connected to both a large valid database of medical knowledge, and the patient record” ([Smith, 1996](#)). More recently, the IOM published *Best Care at Lower Cost: The Path to Continuously Learning Health Care in America* (2012), which calls for transformation of the healthcare system into one that learns from each patient treated and makes the information produced from prior patient encounters (along with evidence from the literature) available at the point of care.

Although progress in healthcare information technology tools is being made, there is significant opportunity to develop, implement, and optimize electronic tools for neonatal care.

Biomedical and Health Informatics

In the 1970s, clinicians with expertise in computers became intrigued by the potential of these tools to improve the practice of medicine, and thus the field of medical informatics was born ([McDonald, 1976](#)). The importance of this field in addressing the issues of information management in health care is growing rapidly, as evidenced by the activities of the American Medical Informatics Association ([AMIA](#); www.amia.org), including the establishment of Clinical Informatics as a subspecialty by the American Board of Medical Specialties (ABMS) in 2011. *Biomedical informatics* can be defined as “the interdisciplinary field that studies and pursues the effective uses of biomedical data, information, and knowledge for scientific inquiry, problem solving, and decision making, driven by efforts to improve human health” ([Shortliffe and Blois, 2014](#)). A more extensive definition can be found at the AMIA website under About AMIA, including professional and training opportunities. The University of Washington (Seattle, Washington, USA) website (<http://bime.uw.edu/>) contains a review of the discipline (found under History, About Us, Vision). The field includes both applied and basic research, with the focus of this chapter being on the applied aspects. Examples of basic research are artificial intelligence in medicine, genome data analysis, and data mining (analyzing data to identify patterns and establish relationships). As our knowledge of the genetic mechanisms of disease expands and more data about patients and outcomes are available electronically, the role of informatics in medicine will expand, particularly in the field of neonatology.

The applied focus of the field in the 1960s and 1970s was data oriented, focusing on signal processing and statistical data analysis. In neonatology, the earliest applications of computers were for physiologic data monitoring in the neonatal intensive care unit (NICU). As the field matured in the 1980s, applied work focused on systems to manage patient information and medical knowledge on a limited basis. Examples include laboratory systems, radiology systems, centralized transcription systems, and, probably the best-known medical knowledge management system, the database of published medical articles maintained by the [National Library of Medicine](#) known first as MEDLARS, then as MEDLINE, and

currently as PubMed (www.ncbi.nlm.nih.gov/pubmed). In addition, neonatologists began to develop tools to aid in the management of patients in the NICU, such as computer-assisted algorithms to help manage ventilators, although the algorithms have not been successfully deployed on a large scale in the clinical setting.

As computers and networking became mainstream in the workplace and home in the 1990s, informatics researchers began to develop integrated and networked systems (Fuller, 1992, 1997). With the explosion of information from the Human Genome Project, the intersection between bioinformatics and medical informatics began to blur, leading to the adoption of the term *biomedical informatics*. The 1990s saw the development of a number of important systems. In terms of patient-specific information retrieval, these systems included integrated electronic medical record systems that in their full implementation can encompass—in a single software application—interfaces to physiologic monitors; electronic flow sheets; access to laboratory and radiology data; tools for electronic documentation (charting), electronic order entry, and integrated billing; and modules to help reduce medical errors. The Internet has permitted ready access and sharing of this information within healthcare organizations and limited secured remote access to this information from home. In terms of patient-population information retrieval, a number of tools were developed to help clinicians and researchers examine aggregate data in these electronic medical records to document outcomes and help to improve quality of care.

The Internet, particularly the World Wide Web, transformed access to medical knowledge (Fuller et al., 1999). Health sciences libraries are increasingly digital, rather than paper repositories. Journals are available online; some are offered exclusively online. Knowledge is available at the point of care in ways that were not previously possible (Tarczy-Hornoch et al., 1997). In 2004, in recognition of the unfulfilled potential of healthcare information technology, the Office of the National Coordinator for Health Information Technology (ONC) was established (<https://www.healthit.gov/>) to achieve the following vision:

Health information technology (HIT) allows comprehensive management of medical information and its secure exchange between health care consumers and providers. Broad use of HIT has the potential to improve health care quality, prevent medical errors, increase the efficiency of care provision, and reduce unnecessary health care costs, increase administrative efficiencies, decrease paperwork, expand access to affordable care, and improve population health.

Throughout the first decade of the 21st century, the focus shifted from demonstrating the promise of electronic medical record and information systems toward implementing them more broadly to realize their benefit (e.g., the ARRA legislation). The pursuit of evidence-based practice can benefit from informatics as an approach to support evaluation of therapeutic recommendations and their implementation (see later discussion) and was part of the ARRA and other approaches to healthcare reform being proposed in 2009. The enormous amount of data being generated through routine use of electronic medical records has the potential to serve as “practice-based evidence,” adding to the medical knowledge base when high quality evidence either doesn’t exist or isn’t applicable to the patient population of interest.

The establishment of Clinical Informatics as a subspecialty in 2011 is further evidence of the evolution of informatics as a medical discipline (Frequently Asked Questions website ([https://](https://www.amia.org/clinical-informatics-board-review-course/faq)

www.amia.org/clinical-informatics-board-review-course/faq). The core content of the subspecialty was defined by AMIA in 2008, and in 2009 the American Board of Preventive Medicine agreed to sponsor the application to the ABMS for Clinical Informatics as a new subspecialty. The ABMS ultimately approved the proposal in 2011, and the first board examination was offered in 2013. In order to sit for the subspecialty boards, candidates must be certified in another ABMS clinical specialty, hold a valid medical license, and (through 2017) qualify either via a practice pathway (at least 25% of a full-time equivalent for 3 years) or the fellowship training pathway. In 2014, the Accreditation Council for Graduate Medical Education (ACGME) released the Program Requirements for Graduate Medical Education in Clinical Informatics, and beginning in 2018, completion of an ACGME-accredited fellowship training program will be required for subspecialty board eligibility (<https://www.amia.org/programs/academic-forum/clinical-informatics-fellowships>).

The practice of neonatal intensive care can clearly benefit from the support of information technology tools; as such, neonatologists have long been involved in informatics. In 1988, as one of the earlier specialties to develop a national database of clinical care, neonatologists established and expanded the Vermont Oxford Network (VON) (www.vtoxford.org) to improve the quality and safety of medical care for newborn infants and their families. As part of their activities, the VON established and maintained a nationwide database about the care and outcome of high-risk newborn infants. Duncan (2015) maintains a continually updated bibliographic database on the history of computer applications in neonatology.

Databases

In broad terms, a database is an organized, structured collection of data designed for a particular purpose. Thus a stack of 3×5 cards with patient information is a database, as is the increasingly rare paper prenatal record. Most frequently, the term *database* is used to refer to a structured electronic collection of information, such as a database of clinical trial data for a group of patients in a study. Databases come in a variety of fundamental types, such as single-table, relational, and object-oriented.

A simple database can be built using a single table by means of a spreadsheet program such as Microsoft Excel or a database program such as Microsoft Access (Microsoft, Redmond, Washington, USA). The advantage of such a database is that it is easy to build and maintain. For an outcomes database in a neonatology unit, each row can represent a patient and each column represents information about the patients (e.g., name, medical record number, gestational age, birth date, length of stay, patent ductus arteriosus [yes/no], necrotizing enterocolitis [NEC; yes/no]). The major limitation of such a database is that a column must be added to store the information each time the researcher wants to track another outcome (e.g., maple syrup urine disease [MSUD]). This limitation can result in tables with dozens to hundreds of columns, which can become difficult to maintain. The challenges can be illustrated with a few examples. One type of challenge results from adding a new column (e.g., MSUD); one must either review all records (rows) already in the spreadsheet for the presence or absence of MSUD or flag all existing records (rows) in the spreadsheet as *unknown* for MSUD status. Another set of challenges results from the logistics of managing an extremely wide spreadsheet – imagine not adding the 10th column but the 1000th column.

The majority of databases and electronic medical records in neonatology are built using relational database software. To build a simple outcomes relational database that permits easy adding of

Tables in the database:

| | | |
|--|--|--|
| DEMOGRAPHIC DATA Name Hospital_Number Gestational_Age Birthdate Admit_Date Discharge_Date | DIAGNOSES Hospital_Number Diagnosis_Code Value | DIAGNOSIS DICTIONARY Diagnosis_Code Description |
|--|--|--|

Example entries in the tables:

| DEMOGRAPHIC DATA | | | | | |
|------------------|-----------------|-----------------|-----------|------------|----------------|
| Name | Hospital_Number | Gestational_Age | Birthdate | Admit_Date | Discharge_Date |
| John Smith | 00-00-01 | 27 | 1/1/2003 | 1/1/2003 | 3/21/2003 |
| Jane Doe | 00-00-02 | 24 | 1/2/2003 | 1/3/2003 | 4/15/2003 |

| DIAGNOSES | | |
|-----------------|----------------|-------|
| Hospital_Number | Diagnosis_Code | Value |
| 00-00-01 | 1 | 1 |
| 00-00-01 | 2 | 1 |
| 00-00-02 | 1 | 2 |
| 00-00-02 | 10234 | |

| DIAGNOSIS DICTIONARY | |
|----------------------|---------------------------------|
| Diagnosis_Code | Description |
| 1 | PDA (1 = small, 2 = large) |
| 2 | NEC (1 = medical, 2 = surgical) |
| | |
| 10234 | Maple Syrup Urine Disease |

• **Fig. 2.1** Example of a Relational Database. *PDA*, patent ductus arteriosus; *NEC*, necrotizing enterocolitis.

new outcome measures, one could use a three-table database design (Fig. 2.1). The DEMOGRAPHIC DATA table contains demographic information for each patient (e.g., Name, Hospital Number [medical record number], Gestational Age). The DIAGNOSIS DICTIONARY table assigns a code number to each diagnosis or outcome being tracked (e.g., patent ductus arteriosus [PDA] = 1; NEC = 2; MSUD = 10234) and defines additional diagnosis descriptors. The DIAGNOSES table links patients (using Hospital Number [i.e., medical record number]) to their diagnoses and assigns a Value to the Diagnosis Code as a descriptor. Adding a new diagnosis to track simply requires adding an entry to the DIAGNOSIS DICTIONARY table. To add a diagnosis to a patient, one would add an entry to the DIAGNOSES table. For example, Girl Smith (medical record number 00-00-01) has a diagnosis of NEC. To add the diagnosis, add to the DIAGNOSES table an entry of “00-00-01” in the Hospital Number column, “2” (the code for NEC) in the Diagnosis Code column, and “2” in the Value column (corresponding to a Description for surgical in the DIAGNOSIS DICTIONARY). Although relational databases are harder to build, they provide greater flexibility for expansion and maintenance and thus are the preferred implementation for clinical databases. They address the challenges in a simple spreadsheet by tracking dates that new diagnostic codes were added and with user interfaces that allow one to easily view only diagnoses present for a given patient rather than all potential diagnoses.

The distinction between a NICU quality assessment–quality improvement (i.e., outcomes) database and an electronic medical record is largely a matter of degree. Some characteristics typical of a neonatal outcomes database are data collection and data entry after the fact, limited amount of data collected (a small subset of

the information needed for daily care), lack of narrative text, lack of interfaces to laboratory and other information systems, and the episodic (e.g., quarterly) use of the system for report generation. Some characteristics typical of an electronic medical record are real-time (many times daily) data entry, a large amount of data collected (approximating all the information needed for daily care in a fully electronic care environment), narrative text (e.g., progress notes, radiology reports, pathology reports), interfaces to laboratory and other information systems, and, most important, the use of the system for daily patient care, including features such as results review, messaging or alerting for critical results, decision support systems (drug dosage calculators, drug–drug interaction alerts, among others), and computerized electronic order entry.

In the past, the majority of neonatal databases and first-generation NICU electronic medical record systems were developed locally by and for neonatologists. A review describing these efforts is available online at www.neonatology.org/technology/computers.html (Duncan, 2015). Unfortunately the majority of these systems were never published or publicly documented, and thus a number of important and useful innovations have been lost or must be repeatedly rediscovered. Anyone considering building their own neonatology database would be well advised to review the existing literature and existing commercial products before embarking on this path. That said, there is room for improvement of the existing products, and neonatologists continue to develop their own databases today. With the trend toward enterprise-wide, interoperable EHRs, it is likely that the market will continue to transition from external niche applications toward a smaller number of major EHR vendors whose applications include integrated neonatology specific tools.

The largest neonatal outcomes database is the centralized database maintained by the VON with the mission of improving the quality and safety of medical care for infants and their families. One of the key activities of the network is their outcomes database, which involves more than 900 participating intensive care nurseries both in the United States and internationally collecting data on over 60,000 very low birth weight infants each year. Other activities of the network are clinical trials, follow-up of extremely low birth weight infants, and NICU quality and safety studies. Although the initial focus of VON was very low birth weight infants (401–1500 g), a newer “Expanded Database” also includes data on infants in neonatal intensive care units weighing more than 1500 g. Currently the network collects data on the majority of very low birth weight infants born in the United States. The databases focus on tracking outcomes. With the passage of the Health Insurance Portability and Accountability Act of 1996 (HIPAA) and federal regulations governing the confidentiality of electronic patient data, some of the anonymous demographic data that were collected by the network in the past have decreased, due to concern that in combination with the identity of the referring center, these data could be used to uniquely identify patients.

Participants in the network submit data and in return receive outcome data for their own institution and comparative data from other nurseries nationwide, including custom reports, comparison groups, and quality management reports. Members also have the ability to participate in collaborative research projects and collaborative multicenter quality-improvement activities. All data except their own are anonymous for all participants. The network does have access to both the individual and aggregate data. The network database is maintained centrally, and data quality monitoring and data entry are centralized. Initially the process involved paper submission of data by participating nurseries. Now, most commercial and custom NICU databases and electronic medical record systems can be used to export much of the information required by the VON, but identification of some clinical details still relies on chart review. Members have the option to submit data electronically in two ways: either directly using the custom eNICQ software developed by VON or by transmitting spreadsheet files to VON for entry into the database.

Certainly, other neonatology outcomes databases exist for purposes ranging from quality improvement to clinical research. Examples include the [Children's Hospitals Neonatal Database](http://thechnic.org/CHND-resources.php) (<http://thechnic.org/CHND-resources.php>) for improving quaternary neonatology care and the [National Institute of Child Health and Human Development \(NICHD\) Neonatal Research Network Generic Database](https://neonatal.rti.org/about/gdb_background.cfm) (https://neonatal.rti.org/about/gdb_background.cfm), which in addition to the clinical trials conducted by the Neonatal Network has been enrolling infants at Network sites in an observational study since 1987.

Electronic Health Record

The EHR, also known as an *electronic medical record*, is much more complex than an outcomes database, because the system is intended to be used continually in real time to replace electronically some, if not all, of the record keeping, laboratory result review, and order writing that occur in a NICU (or more generically in any inpatient or outpatient clinical setting). The complexity of this task becomes evident if one imagines that, for a paperless medical record environment, every paper form in a nursery would need to be replaced with an electronic equivalent. Even more challenging is the

conversion of each paper-based workflow element and process into an electronic one.

Most US healthcare organizations have adopted EHR functionality because of a combination of forces, such as the desire to reduce error and to control the spiraling costs of health care. These reasons were addressed at great length in two reports from the IOM ([Institute of Medicine Committee on Improving the Patient Record, 1997](#); [Kohn et al., 2000](#)). Benefits are typically achieved when information is available electronically (e.g., results of laboratory tests, radiology procedures, transcription) and input into the system (e.g., problem lists, allergies) and when both sets of information are combined and checked against electronic orders. The adoption of computerized provider order entry (CPOE) has been shown to reduce errors and affect care provider behavior ([Radley et al., 2013](#)). Combining just electronic laboratory results (e.g., creatinine level) and electronic order entry (e.g., a drug order), for example, enables one to verify that drug dosages have been correctly adjusted for renal failure. This approach is more straightforward in adults, but in neonates, whose renal function is more difficult to assess and for whom drug dosage norms depend on gestational age and post-delivery age, the system must be able to capture additional information (e.g., urine output, gestational age) and requires more sophisticated logic. Nearly two decades following the aforementioned Institute of Medicine reports, and supported by stimulus funding through the ARRA HITECH act, nearly 75% of US hospitals have implemented CPOE ([Healthcare Information and Management Systems Society, 2016](#); [Adler-Milstein, 2015](#)).

Results of review systems include basic demographic data, such as name, age, and address from the hospital registration system. These systems require a moderate amount of work to tie them to the various laboratory, radiology, and other systems and to train users. The benefits are hard to quantify, but users typically prefer them to the paper alternative because of the more efficient access to information. The challenge in moving beyond the results review level to the integrated system level is that some degree of electronic documentation and CPOE are essentially prerequisites but are challenging to implement in terms of both human and financial costs. Implementation of integrated systems requires significant work, including infrastructure demands like the presence of computers at each bedside and network availability, as well as significant effort to educate and train users. The benefits accrue mainly to the organization, in the form of reduced costs of filing, printing, and maintaining paper records and, if providers enter notes electronically instead of dictating them, significant savings in transcription costs. Unfortunately, much of the burden of integrated systems is passed on to end users, who often find that it takes much longer to do their daily work with electronic documentation. Without implementation of CPOE and associated clinical decision support (CDS) systems, the users and patients do not realize major day-to-day benefits.

The benefits of EHR adoption start to accrue more clearly at the next level of electronic order entry. The complexity of implementing and deploying an electronic order entry system cannot be overstated. Interfaces need to be built with all the systems that are part of results review in addition to other systems. Furthermore, a huge database of possible orders must be created. Finally, and most important, training end users presents a significant challenge, because writing orders electronically is more complex and time consuming than writing them by hand. The change in management issues becomes apparent when one considers that typically these systems take the unit assistant out of the loop; therefore much of the oversight that can occur at the unit assistant level does not,

or the burden of oversight is borne by the person entering the orders. Further complicating matters, despite the mitigation of issues like illegibility and order of magnitude math errors, CPOE systems introduce new types of errors, such as juxtaposition errors (e.g., clicking on the wrong patient or selecting the wrong order in a list) (Ash, 2007; Longhurst et al., 2013).

After overcoming the barriers to electronic order entry, organizations can start to benefit from integrated systems. For this reason, the trend today is not a stepwise move from results review to documentation of integrated systems. Instead, organizations are moving from results review directly to integrated systems. Interestingly, the technical complexities and the training and usage complexities of integrated systems are not much higher than those for order entry. Integrated systems add tools to make life easier for care providers using all the data in the system. As an analogy, an integrated EHR system is like an office software suite that encompasses a word processor, a spreadsheet, a slide presentation tool, a graphic drawing tool, and a database, all of which can communicate with one another, making it easy to put a picture from the drawing tool or a graph from a spreadsheet into a slide show.

Integrated systems include (1) checking orders for errors, (2) alerts and reminders triggered by orders or by problems on the problem list or other data in the system, (3) care plans tied to patient-specific information, (4) charting modules customized to the problem list, (5) charting and progress notes that automatically import information (e.g., from laboratory tests, flow sheets) and that help generate orders for the day as the documentation occurs, (6) modules to facilitate hyperalimentation ordering, and (7) modules to assist in management (Palma et al., 2011b, 2011c; Palma and Arain, 2016). For example, a system could be configured such that reminders for screening studies (e.g., for retinopathy of prematurity, intraventricular hemorrhage, and brainstem auditory evoked response) are triggered by gestational age, a problem list, and previous results of screening studies. Similarly, admitting a neonate at a particular gestational age with a particular set of problems could trigger pathways, orders, and reminders specific to that clinical scenario. An important caveat is that all such systems are only as good as the data and rules put into them. The issues raised in the section on evaluation of therapeutic recommendations are important to consider in the context of electronic order entry and integrated systems. Additionally, enterprise-wide (non-niche) EHRs are not sufficiently configured out of the box for optimal care of critically ill and premature neonates.

The EHR market is continually evolving; this is true of products designed specifically for the NICU and more generic products designed to be used throughout a hospital or healthcare system. The ONC was established, in part, to affect the EHR marketplace by creating standards and certification bodies. In particular, the ONC created the Certification Commission for Healthcare Information Technology (CCHIT) and the Health Information Technology Standards Panel to begin to bring more standardization to the marketplace. The CCHIT examined criteria for certifying systems, including functionality, security, and interoperability. Facilitated by ARRA HITECH incentives, integrated systems are becoming more broadly implemented. However, the needs of different healthcare systems and the clinical services within a single health system vary significantly; in general, existing products are not configured to meet all these needs out of the box. Furthermore, the trend among healthcare organizations, EHR developers, and vendors is to move away from niche systems tailored to particular subsets of care providers, such as neonatology, and toward a focus

on systems that are generically useful. There are two important drivers behind this trend.

The first and most important reason for adopting a single integrated system is that the benefits of an EHR system begin to accrue only when an entire organization uses the same one. Consider the following scenario: a woman receives prenatal care in the clinic of an institution and is then admitted to the emergency department in preterm labor. Her infant is delivered in the labor and delivery department, hospitalized in the NICU, and discharged to an affiliated pediatric follow-up clinic. In the era of paper medical records, paper is used to convey information from one site to the other. In an integrated EHR system, all the information for both mother and infant is in one place for all providers to see. Interoperability is important as well if the care described crosses organizational boundaries, such as an outpatient-focused health maintenance organization contracting inpatient obstetric care to one hospital system and neonatal or pediatric care to a children's hospital in a different healthcare system. If a single unified institution were to adopt niche software tailored to the needs of each site, a provider caring for the infant might need to access an emergency department system, an obstetric system, a NICU system, and an outpatient pediatric system to gather all the pertinent information. Each system would require the user to learn a separate piece of software. Learning a site-specific piece of software is a considerably greater burden on care providers than learning to use a site-specific paper form. If care crosses organizations with electronic systems that are not interoperable, then care transitions most often remain on paper.

The second factor driving adoption of integrated systems is economies of scale. The ideal EHR system contains electronic interfaces that automatically import the system data from laboratory, pharmacy, radiology, transcription, integrated electronic orders, error checking, and electronic documentation by care providers. Given that development of these interfaces, training, and maintenance cost more than the purchase of the software itself, it is far more cost-effective to install one system with one set of interfaces and one set of training and maintenance issues than to replicate the process multiple times.

The neonatal intensive care environment poses some unique challenges for EHRs. As a result, it is important to ensure that when healthcare systems are making decisions about the purchase of an EHR, neonatologists and other neonatal healthcare providers are involved in the process. An excellent source of historical information about NICU medical record systems and databases is an article by Stavis (1999). More recently, Palma et al. reviewed several aspects of EHRs related to neonatology, including computerized provider order entry (Palma et al., 2011a), handoffs (Palma et al., 2011c), and clinical data entry and display (Palma et al., 2012b). Neonatal care providers who are helping to select an EHR system should acquire the necessary background knowledge through reading some basic introductory texts on medical informatics, focusing on EHRs. It is then critical that they survey other organizations similar to their own to understand the benefits and drawbacks of various EHR systems for neonatal care. For example, the needs of a level III academic nursery that performs extracorporeal membrane oxygenation are different from those of a community level II hospital that does not perform mechanical ventilation. Systems that work well in teaching hospitals with layers of trainees may not work well in private practice settings and vice versa. Importantly, when using a medical informatics framework, neonatal care providers should develop a list of prioritized criteria specific to their institution and evaluate available products in the marketplace using this list, while also considering whether the system meets CCHIT standards as described earlier.

All end users' needs must also be considered. If residents, nurse practitioners, nutritionists, pharmacists, and respiratory therapists are expected to use the system, their input must be solicited. Ensuring broad-based input is especially relevant as the EHR system is likely to require significant data entry by healthcare providers (e.g., electronic nursing and respiratory therapist [RT] documentation, note writing, medication administration records, order entry). Involvement of all stakeholders is an important component of change management; in addition, following implementation, their input is critical for optimizing the system for care in the NICU. Unfortunately there is little literature on this issue, because institutions rarely publicize and publish their failures in this arena, although the situation is beginning to change. A review of some of these challenges and a theoretical framework for looking at them is provided by Pratt et al. (2004), and an evidence-based approach to mitigating unintended consequences of EHR implementation is discussed by Longhurst et al. (2013).

The final step in evaluating and testing a potential system is to develop a series of scenarios and to have potential users test the scenarios. Evaluating usage scenarios prior to vendor selection typically involves visits to sites that have installed the EHR system under consideration. An example scenario might be for a nurse, a respiratory therapist, a resident, and an attending physician to try to electronically replicate, on a given system under consideration, the bedside charting, progress note charting, and order writing for a critically ill patient who undergoes extracorporeal membrane oxygenation from hospital admission through decannulation. Developing and testing such scenarios are the best way to ensure that aspects of charting, note writing, and documentation unique to the NICU are supported by the system.

Evaluating Therapeutic Recommendations

Once all the data about a patient, whether in electronic or paper form, are in hand, the clinician is faced with the challenge of medical decision making and applying all that he or she knows to the problem. It is vital that clinicians understand what is known and what is still uncertain in terms of the validity of therapeutic recommendations. The evaluation of new recommendations arising from a variety of sources, including journal articles (Fig. 2.2), metaanalyses, and systematic reviews, is a critical skill that all neonatologists must master. Broadly speaking, this approach has been termed *evidence-based medicine*. Although a full discussion is beyond the scope of this chapter, there are two outstanding sources of information on the subject, one by Guyatt and Rennie (2015) and the other by Straus et al. (2010). A useful discussion of clinical practice guidelines as they relate to neonatology is provided by Polin and Lorenz (2015). An important caveat is that evidence-based medicine is not a panacea. It is not helpful when the primary literature does not address a particular clinical situation, such as one that is rare or complex. This approach also does not necessarily address broader concerns, such as clinical importance or cost-effectiveness, although it sometimes does. There are potential challenges when combining evidence-based medicine with the emerging humanistic approach to health care, which can heavily weight patient preferences potentially over the evidence base.

In the early days of medicine, the standard practice was observation of individual patients and subjective description of aggregate experiences from similar patients. As the science of medicine evolved, formal scientific methods were applied to help to assess possible therapeutic and management interventions. Important tools in this effort are epidemiology, statistics, and clinical trial design. Currently medicine in general and neonatology in particular are

• **Fig. 2.2** Yearly Citation Totals From 2015 MEDLINE/PubMed From 1970 to 2016. (Redrawn from https://www.nlm.nih.gov/bsd/licensee/2017_stats/2017_Totals.html.)

faced with an interesting paradox. For some areas, there is a wealth of information in the form of randomized controlled clinical trials, whereas for others, there is scant information to guide clinical practice. A wealth of well-designed clinical trials on the use of surfactant have been published, for example, but there are essentially no trials addressing the management of chylothorax. The lack of studies of (and therefore evidence for) treatments in neonatology has led to newborns being described as “therapeutic orphans” (Stiers and Ward, 2014).

One might assume that the practice of medicine reflects the available evidence, but this is not the case. McDonald (1996) summarized the problem as follows: “Although we assume that medical decisions are driven by established scientific fact, even a cursory review of practice patterns shows that they are not.” A study of 3000 treatments (as reported in randomized controlled trials) in the *British Medical Journal's* Clinical Evidence database (<http://clinicalevidence.bmj.com>) shows that, as of 2016, 50% of treatments are of unknown effectiveness, 11% are clearly beneficial, 24% are likely to be beneficial, 7% are a tradeoff between beneficial and harmful, 5% are unlikely to be beneficial, and 3% are likely to be ineffective or harmful (Fig. 2.3). As a result, neonatologists have a responsibility to identify what knowledge is available in the literature and elsewhere and to critically evaluate this information before applying it to practice. Furthermore, because this information is constantly evolving, practitioners must continually revisit the underlying literature as it expands (e.g., the recommendations regarding the use of steroids for chronic lung disease).

For the 50% of treatments with known (whether beneficial or harmful) effectiveness, the evidence-based practice of medicine is an approach that addresses these issues. It is helpful to consider the process as involving two steps: first, a critical review of the primary literature and second, the synthesis of information in the primary literature to determine the implications on one's practice. Most neonatologists have significant experience with critical review of the literature through journal clubs and other similar forums. The approach involves systematically reviewing each section of an article (i.e., background, methods, results, discussion) and asking critical questions for each section (e.g., for the Methods section: Is the statistical methodology valid? Were power calculations made? Was a hypothesis clearly stated? Do the methods address the hypothesis? Do the methods address alternative hypotheses? Do the methods address confounding variables?). The formal evaluation of each section must then be synthesized into conclusions. A helpful

Effectiveness of 3000 treatments as reported in randomized controlled trials selected by Clinical Evidence. This does not indicate how often treatments are used in healthcare settings or their effectiveness in individual patients.

• **Fig. 2.3** Effectiveness of 3000 Treatments Reported in Randomized Controlled Trials. (Redrawn from <http://clinicalevidence.bmj.com/x/set/static/cms/efficacy-categorisations.html>.)

question to ask is, “Does this paper change my clinical practice, and if so, then how?” Additional resources for systematic review of the primary literature are listed in the Suggested Readings. It is important to note that guidelines for systematic review of a single article differ according to whether it describes a preventive or therapeutic trial (e.g., use of nitric oxide for chronic lung disease), evaluation of a diagnostic study (e.g., use of C-reactive protein level for prediction of infection), or prognosis (e.g., prediction of outcome from a Score for Neonatal Acute Physiology score).

The second, and arguably more important, step is to determine not the effect of one article on one’s practice but the overall effect of the body of relevant literature on one’s practice. For example, if the preponderance of the literature favors one therapeutic recommendation, then a single article opposing the recommendation must be weighed against the other articles that favor it. This task is complex, and the most complete and formal statistical approach to combining the results of multiple studies (i.e., metaanalysis) requires significant investment of time and effort. Part of the evidence-based practice of medicine approach therefore involves the collaborative development of evidence-based systematic reviews and metaanalyses by communities of care providers. Within the field of neonatology, Sinclair et al. (1992) laid the seminal groundwork for this approach; their textbook *Effective Care of the Newborn Infant* remains an important milestone, but it illustrates the problem of information currency. Because the book was published in 1992, none of the clinical trials in neonatology in the last decade and a half are included. The Internet has permitted creation and continual maintenance of up-to-date information by a distributed group of collaborators, lending itself well to the maintenance of a database of evidence-based medicine reviews of the literature. This international effort is the Cochrane Collaboration, which began in 1993 with the *Cochrane Neonatal Review*. A limitation of the Cochrane approach is illustrated by the relatively restricted scope of topics covered at the NICHD website (<https://www.nichd.nih.gov/cochrane/Pages/default.aspx>). The existence of a review requires adequate literature on a topic and a dedicated and committed clinician to create and update the review.

It is important to distinguish between these formal approaches to reviewing the literature (i.e., systematic literature reviews and metaanalyses) that have specific methodologies and more ad hoc reviews of the literature. Evidence-based medicine aggregate resources such as the Cochrane Collaboration take a more systematic approach, but review articles published in the literature vary in their approach. Metaanalyses are easy to distinguish, but systematic reviews versus

ad hoc reviews are harder to distinguish. Systematic reviews focus on quality primary literature (e.g., controlled studies rather than case series or case reports) and must include a Methods section for the review article that (1) explicitly specifies how articles were identified for possible inclusion and (2) the criteria used to assess the validity of each study and to determine whether to include or exclude primary literature articles in the systematic review. Systematic reviews also tend to present the literature in aggregate tabular form, even when metaanalyses of statistics of all the articles cannot be done. One commonly used source of overview information in neonatology—the *Clinics in Perinatology* series—is a mix of opinion (written in the style of a book chapter), ad hoc literature review, systematic literature review, and metaanalysis. Clinical practice guidelines (e.g., screening recommendations for group B streptococcal infection), although based on a primary literature review, are typically neither metaanalyses nor systematic reviews of the literature. Whereas formal methods are used to derive conclusions with metaanalyses and systematic reviews, frequently guidelines are developed instead by consensus among committee members; this is true of both national and local practice guidelines. General textbooks of neonatology are typically based on ad hoc literature reviews that include both primary literature and systematic literature reviews. When reading overviews of the aggregate state of current knowledge on a given topic in neonatology, it is important to keep these distinctions in mind.

Anyone interested in developing evidence-based reviews on a particular topic should review the textbooks on evidence-based practice referenced at the end of this chapter. Initially, it is a good idea to collaborate with someone with experience in systematic review and metaanalysis. The process consists of the following steps: (1) identifying the relevant clinical question (e.g., management of bronchopulmonary dysplasia); (2) narrowing the question to a focus that enables one to determine whether a given article in the primary literature answers it (e.g., does prophylactic high-frequency ventilation have positive or negative effects on acute and chronic morbidity – pulmonary and otherwise?); (3) extensively searching the primary literature (frequently in collaboration with a librarian with expertise searching the biomedical literature) and retrieving the articles; (4) critically, formally, and systematically reviewing each article for inclusion, validity, utility, and applicability; and (5) formally summarizing the results of the preceding process, including conclusions valid throughout the body of included primary literature.

Online Resources

A number of online resources are valuable for neonatologists. For accessing the primary literature, the most valuable resource is the National Library of Medicine’s database of the published medical literature accessible (PubMed; www.ncbi.nlm.nih.gov/pubmed) along with many other databases accessible from the Health Information Website (www.nlm.nih.gov/hinfo.html). The PubMed system is continually being enhanced; therefore it is useful to review the help documentation online and regularly check the New/Noteworthy section to see what has changed. One of the most powerful yet underused tools is the Similar Articles tool that is available as a link below each article listed on PubMed and is visible as a list adjacent to an article or abstract as it is being viewed (Liu and Altman, 1998). The PubMed system applies a powerful statistical algorithm to each word in the title, each author, each major and minor keyword (Medical Subject Heading terms), and each word in the abstract in order to find similar articles in the database. In general,

this system outperforms novice-to-advanced healthcare providers performing a complex search and approaches the accuracy of an experienced medical librarian. Another powerful search tool within PubMed is the Clinical Query (www.ncbi.nlm.nih.gov/pubmed/clinical). This tool facilitates searches for papers by clinical study category (e.g., etiology, diagnosis, therapy, prognosis), focuses on systematic reviews, and performs Medical Genetics searches – the last of which is particularly useful in the context of neonatology. All the major pediatric journals are available online either through a package at local hospital libraries or by subscription, instead of or in addition to a print subscription. The best free online source of information on evidence-based practice is the *Cochrane Neonatal Review*. Subscriptions to the full Cochrane database can be purchased online as well.

Given the growing role of genetics in health care, and the particular importance of genetic diseases in infants, two notable genetics databases are available free of charge online (in addition to the Medical Genetics search within PubMed Clinical Queries). The first is *Online Mendelian Inheritance in Man* (www.ncbi.nlm.nih.gov/omim). This database, which is a catalog of human genes and genetic disorders, is an online version of the textbook by the same name. It is a diachronic collection of information on genetic disorders, meaning that each disease entry chronologically cites and summarizes key papers in the field. The second is *GeneTests* (www.genetests.org), a directory of genetic testing (what testing is available on a clinical and research basis, where, and how one sends a specimen) and a user's manual (how to apply genetic testing). The user's manual section consists of entries for a growing number of diseases or clinical phenotypes of particular importance. Entries are written by experts, peer reviewed both internally and externally, subjected to a formal process similar to a systematic review, and updated regularly online. As of the spring of 2016, the GeneTests database includes GeneReviews (user's manual entries) for 658 diseases, and the directory includes 1067 genetics clinics, 680 laboratories, and information on 79,004 tests for 4548 diseases covering 5385 genes.

An excellent site that maintains links to the majority of locally developed, neonatology-specific content around the country is maintained by Duncan (2015). In addition to a database of links to clinical resources around the country, the site also has a job listing and a database of the literature on computer applications in medicine.

The clinician must realize that, unlike journals, textbooks, and guidelines, material on the World Wide Web (whether accessed from Duncan's site or using a search engine) is not necessarily subject to any editorial or other oversight; therefore as stated by Silberg et al., as early as 1997, "caveat lector" (reader beware). A number of articles and online resources address criteria for assessing the validity and reliability of material on a website (*Health on the Net Foundation*, www.hon.ch; *American Public Health Association*, 2001). With caution in mind, a search of the World Wide Web using a sophisticated search engine (e.g., Google, Google Scholar) can yield valuable information, though search results typically include a lower proportion of quality resources compared with curated resources.

Future Directions

Computers and biomedical informatics continue to play an increasing role in neonatology – for information management and because EHRs are fundamental to the provision of clinical care (Palma, 2012a). While significant levels of EHR adoption have been achieved in the United States, the benefits of digitizing the medial record

are not yet fully realized, and both providers and patients are keenly aware of the challenges and shortcomings of many current computer-based workflows (Toll, 2012; Wachter, 2015).

One significant and largely unrealized opportunity of EHR adoption is the generation of new knowledge from the vast amounts of clinical data collected electronically (McGregor, 2013). As stated previously, the *British Medical Journal's* Clinical Evidence database suggests that 50% of treatments (likely an even greater proportion in neonatology) are of unknown effectiveness. These "gaps in the evidence—where there are no good (randomized controlled trials [RCTs]) or no RCTs that look at groups of people or at important patient outcomes" (BMJ Clinical Evidence)—represent areas of opportunity. It is not possible for all of these gaps to be filled by RCTs, a study design that may not be feasible for the treatment or population of interest. On the other hand, with the increasing adoption of EHRs, a wealth of clinical data is being collected as a byproduct of routine care (so-called *practice-based evidence*).

The 2012 IOM report *Best Care at Lower Cost: The Path to Continuously Learning Health Care in America* (2012) calls for and outlines an approach to transformation of the healthcare system into one that learns from practice-based evidence, generating knowledge from earlier patient encounters and making it available (along with evidence from the literature) at the point-of-care. Steps toward the concept of a continuously learning healthcare system are being made, with some examples of practice-based evidence being used for improvement in neonatal care (Spitzer et al., 2010; Gale and Morris, 2016; Palma and Arain, 2016). Capitalizing upon clinical data generated in EHRs for the purposes of discovery and improved care will increasingly become a focus of biomedical informatics in neonatology.

Ethics, Data, and Policy in Newborn Intensive Care

WILLIAM L. MEADOW AND JOHN D. LANTOS

Philosophy

Ethics in the neonatal intensive care unit (NICU), as in all clinical contexts, starts with the traditional triangular framework of principles. We consider autonomy (do what the patient, or in this case the parent, thinks is right), paternalism (do what the doctor thinks is right), and the complementary concepts of beneficence and nonmaleficence (do the right thing). These principles, independent of context or data, are timeless. Many applications of these traditional ethical principles occur daily in the NICU (e.g., avoid futility, do not torture, and intervene when the data provide compelling evidence to do so).

The problem with timeless principles is that we all have to act in real time and, sometimes, in real time, the timeless principles conflict with one another and we have to decide quickly which compromises or combinations are best. What exactly is the right thing? What facts should be brought to bear in the decision? What weight should be given to each fact? And whose opinion should count in the end? Unfortunately, much of NICU care falls between the relatively straightforward decisions to not resuscitate babies born at 21 weeks, providing obligatory support to babies born at 28 weeks, or not performing cardiopulmonary resuscitation on infants with lethal anomalies. Faced with a difficult case, it is rare that simply applying principles will help to devise a solution. Difficult cases are usually ones in which the principles themselves are in conflict, or their application to the case is ambiguous.

The traditional ethical solution to medical dilemmas is to ground concerns in context, take data into account, and be sympathetic to patient preferences when the balance of benefits and burdens is not clear.

In the NICU, health professionals are constantly and anxiously aware that the burdens of treatment are real, immediate, long term, and significant, whereas the benefits of NICU interventions are distant, statistical, and unpredictable. Babies must undergo months of painful procedures such as intubation, ventilation, and intravenous catheterization. Often, they are left with lifelong sequelae. How should we decide whether we did the right thing in order to help decide whether, in similar circumstances, we should again do the same thing?

NICU success is often viewed as “all or none.” In most of the NICU follow-up literature a Bayley Mental Developmental Index (MDI) or Psychomotor Developmental Index (PDI) greater than 70 is classified as *normal*, whereas an MDI or PDI less than 70 is

classified as an *adverse outcome*. We strongly disagree with this dichotomization. There is no single measure of success or failure. Each baby is different, each family is different, and each life course is different.

In order to make good decisions, we need good data.

Getting Good Data

What kind of information would parents, physicians, or judges want to know about the babies in the NICU in order to decide when treatment ought to be obligatory and when it ought to be optional?

The essential truth at the intersection of NICU epidemiology and ethics is that survival depends sharply on gestational age (GA), within relatively precise boundaries. In the United States, as in virtually all the industrialized world, infants born after 25 weeks' gestation have survival rates that are high enough that treatment is generally considered obligatory. For these infants, the ethical principle of best interests requires their resuscitation, in the same way that sick children born at term deserve resuscitation.

Conversely, for infants born before 22 weeks' gestation, survival is essentially zero. Consequently, these infants and their parents deserve our compassion but not our interventions, on the ethical grounds of strict futility.

In between, spanning roughly one gestational month, from 22–25 weeks, we will require not only data but also interpretation. Tyson et al. (2008), using the vast database of the National Institute of Child Health and Human Development network, attempted to go “beyond gestational age” and quantify additional risk factors for both mortality and neurologic morbidity in infants born on the cusp of viability. Their analysis revealed that singleton status, appropriate in utero growth, antenatal steroids, and female gender all improve the likelihood of survival and intact neurologic outcome, independent of GA. By considering these other factors, all of which are available at the time of birth, doctors are able to more accurately estimate the chances that a baby will survive or that survivors will have neurodevelopmental impairment.

However, two problems remain. First, for many infants the predictive value of the Tyson algorithm is still not very good – that is, many of the lower-risk patients will still die, and many of the higher-risk patients will survive. Second, the Tyson algorithm, like GA, ignores a potentially important feature of NICU care – time. The algorithm uses only data that are available at the time of birth.

It does not account for prognostic features that might become available as the infant's course unfolds in the NICU. This is an important limitation that has ethical implications.

There are distinct advantages to making decisions over the first few days of the NICU stay, rather than in the delivery room at the time of birth. The first is emotional. Parents often appreciate the opportunity to get to know their baby as an individual, as opposed to making decisions based only on the anonymous population-based prognostications that are available at the time of birth. Second, there is valuable information to learn while the baby is in the NICU. Two time-sensitive prognostic features have been evaluated in the context of infants born at the border of viability – serial illness severity algorithms (Score for Neonatal Acute Physiology [SNAP]) and intuitions that the patient would “die before NICU discharge” (Meadow et al., 2008). Unfortunately, although SNAPS on the first day of life have good prognostic power for death or survival, their power diminishes over time. Intriguingly, serial intuitions that an individual baby will die before discharge – offered by medical caretakers for patients who require mechanical ventilation and for whom there is an ethical alternative to continued ventilation, namely extubation and palliative care – are remarkably accurate in predicting a combined outcome of either death or survival with neurologic impairment (MDI or PDI <70). Babies with abnormal results from a cranial ultrasound examination whose doctors agree with one another that the babies are likely to die have a less than 5% chance of surviving with both MDI and PDI greater than 70 at 2 years, independent of their GA. The predictive power of these data, acquired over time during an individual infant's NICU course, though not perfect, is greater than any algorithm available at the time of birth.

What do prospective parents or medical caretakers consider when they are asked to decide whether or not to resuscitate their micro-preemie? They may not want the precise prognostic estimates that we try to offer. For many parents, the death of their baby in the NICU is not necessarily the worst outcome. Instead, it may be worse to not even try to save the baby. That decision may leave parents with a life of self-doubt about whether, had they only tried, their baby might have survived. For such parents, trying and failing might be preferable to not trying at all.

If trying and failing is seen as a positive process, then the preferable choice might best be made not by looking at the percentage of intact survivors among all births (the current practice in many studies, including the model, noted above, developed by Tyson et al.) but instead as a function of only those infants who survive to discharge.

Numerous studies analyzing various populations in several countries have converged on the same surprising observation: the incidence of neurologic morbidity in NICU survivors is not very different when comparing infants at 23, 24, 25, and 26–27 weeks' gestation. The essential epidemiologic difference for infants born in this gestational range appears to be whether the baby will survive at all. Once the baby leaves the NICU, the risk of severe morbidity is largely the same; this is true in single-center and multicenter studies, in the United Kingdom, Canada, Europe, and the United States (Tyson et al., 2008; Johnson et al., 2009). Paradoxically, if avoiding survival with permanent crippling neurologic injury is the driving force behind resuscitation decisions, it appears that we should not be worrying about 23- and 24-weekers; rather we should not be resuscitating 26- or 27-weekers. Many more of these more mature babies will survive. Thus even if the rate of disability among survivors is lower, the absolute number of survivors with disability will likely be higher.

A fascinating insight has been offered by Janvier et al. (2008), who have done extensive surveys comparing responses to requests for resuscitation of sick micro-preemies with resuscitation of comparably sick patients at other ages (from term infants to 80 year olds). Consistently, it appears that micro-preemies are devalued – that is, for comparable likelihood of survival and comparable likelihood of neurologic morbidity in survivors, more people would let a micro-preemie die first or at least offer to resuscitate them last. There is no theory to account for these findings.

Finally, there is epidemiologic difficulty in assigning value to morbidity in surviving infants in the NICU. Verrips et al. (2008) have attempted to assess the effects of permanent residual disability for NICU survivors and their immediate families; they have demonstrated consistently that children with disabilities and their parents place a much higher value on their lives, and the quality of those lives, than do either physicians or NICU nurses. The vast majority of infants who survive the NICU, even those with significant permanent neurologic compromise, have “lives worth living,” as judged by the people most affected by those lives.

GA-specific mortality seems to preclude resuscitation for infants born before 22 weeks' gestation and require resuscitation for infants born after 27 weeks' gestation. In between, the outcomes are murky, prognostic indices are imperfect, and sociologic analyses of human behaviors (of parents and physicians) appear inadequate to develop any uniform approach that is satisfactory.

Public Policy: the Baby Doe Case

In the 1980s, the federal government attempted to change the rules for neonatal decisions about babies with congenital anomalies.

In 1982, a baby with Down syndrome and esophageal atresia was born in Bloomington, Indiana (USA). Baby Doe's parents refused to consent to surgery and chose palliative care instead. The court sided with the parents. The doctor and hospital appealed. The Indiana Supreme Court refused to hear the appeal, and the baby died after 8 days (Lantos, 1987).

This led to a national controversy that eventually resulted in amendments to the federal Child Abuse and Treatment Act (Annas, 1986; Kopelman, 1988). While this law has limited authority in regulating clinical decisions, it symbolically endorses the idea that life-sustaining treatment should not be withheld only on the basis of anticipated disability.

There is still controversy when treatments enable survival but have a high likelihood, or certainty, that survival will be accompanied by severe neurologic impairment. As a result, two questions must be asked: How severe will the neurologic impairment be? What is the likelihood that the child will have the most severe possible impairment?

The shift in moral standards regarding babies with Down syndrome was not related to technology but rather sociology. The capacity to repair Arnold–Chiari malformation and duodenal atresia existed long before it was applied to children with myelomeningocele and Down syndrome. What has changed the mood of the country is a growing recognition that disability is as much a social construct as a medical construct, although it is always both and not one or the other.

Malpractice Cases Against Neonatologists

There are also malpractice cases against neonatologists that have shaped the decision-making climate in the NICU. In one, Miller

versus Hospital Corporation of America Inc. (2003) the doctors were sued for resuscitating a tiny preemie over the objections of the parents. The case focused on events that had occurred in 1990, when Mrs. Miller came to a Hospital Corporation of America hospital in Texas in labor at 23 weeks' gestation. The fetus was estimated to weigh 500–600 g. No baby born that size had ever survived at that hospital. Mrs. Miller, her husband, and the attending physicians agreed that the baby was previable and that no intervention was indicated. The baby was born, but a different physician performed resuscitation, and the infant survived with brain damage. As a result, the Millers sued the hospital for a breach of informed consent and were awarded \$50 million by a trial jury. The case wound its way to the Texas Supreme Court, which dismissed the verdict and articulated an “emergency exception” for physicians – that is, if a Texas physician finds himself or herself in the emergency position of needing to resuscitate a patient to prevent immediate death, the physician can try to perform resuscitation without being obligated to obtain consent from anyone. Whether it would be acceptable for a physician not to perform resuscitation in an emergency was left unarticulated by the Texas court.

In Wisconsin, the case of *Montalvo versus Borkovec* (2002) took the legal obligations of neonatologists and parents to a different place. The case derived from the resuscitation of a male infant born between 23 and 24 weeks' gestation, weighing 679 g. The parents claimed a violation of informed consent, arguing that the decision to use “extraordinary measures” should have been relegated to the parents. The Wisconsin Appellate Court disagreed, holding that “in the absence of a persistent vegetative state, the right of a parent to withhold life-sustaining treatment from a child does not exist.” Because virtually no infant is born in a persistent vegetative state, this decision would apparently eliminate the ethical possibility in Wisconsin of a “gray zone” of parental discretion. No other jurisdiction in the United States has adopted this position. The Wisconsin Appellate Court, like the Texas Supreme Court, was silent on whether physicians have discretion not to resuscitate. However, in Texas and Wisconsin, physicians are apparently not liable if they choose to do so.

A number of other state courts have addressed issues of treatment or nontreatment. In general, the courts are permissive of physicians who resuscitate infants. If courts are asked to sanction decisions to allow infants to die, most will do so only if there is consensus among physicians and parents and occasionally ethics committees. Courts are not eager to punish physicians who treat infants over parental objections or to empower physicians to stop treatment when parents want it to continue.

Future Directions

A number of recent developments may change the way we think about ethical issues in the newborn period. These include the rise of fetal medicine and expanded genomic screening of newborns.

Fetal Medicine Centers

Many children's hospitals are now developing fetal medicine centers. The goal of these centers is to identify fetuses at risk – particularly those with congenital anomalies – and to care for those fetuses and their mothers in centers where there is expertise in fetal diagnosis, therapy, and neonatal care. The hope is that such centers will allow more timely, and therefore more effective, intervention for babies with congenital heart disease, congenital diaphragmatic hernia, or other anomalies.

The medical effectiveness of these fetal medicine centers will depend on two distinct developments. First, on a population basis, these centers will only be as effective as fetal screening and diagnosis. The existence of these centers will almost certainly create an expectation and a demand for better fetal screening. Such screening is likely to include both better imaging and better screening tests that can be performed on maternal blood; both will lead to earlier diagnosis of fetal anomalies. These diagnoses will create more complex dilemmas for perinatologists and parents who will need to decide, in any particular case, whether to terminate the pregnancy, offer fetal therapy, or offer either palliative care or interventions after birth. Ironically, better fetal diagnosis may increase the likelihood of pregnancy termination, even when postnatal treatment is possible, such as in hypoplastic left heart syndrome.

Second, the effectiveness of fetal centers will depend on the effectiveness of fetal interventions. To date, fetal interventions have only been effective in a relatively few conditions. Vascular ablation for twin-to-twin transfusion syndromes clearly improves outcomes in these conditions. In utero surgery for myelomeningocele also leads to better outcomes for babies born with this condition. The vast majority of prenatally diagnosed conditions cannot be treated in utero. The real hope of fetal medicine centers today is that they will improve outcomes by allowing better planning for perinatal interventions. In some cases, that may lead to changing the timing or mode of delivery. In other cases, it may mean that a team of pediatric subspecialists will be prepared and immediately available to treat the baby in the minutes after birth. These sorts of efforts may improve outcomes.

Expanded Newborn Screening

In recent years, the number of diseases and conditions that can be diagnosed through newborn screening has expanded dramatically. Such screening is under the purview of states, rather than the federal government, and there is wide variation in the number of tests that are performed. In 1995 the average number of tests per state was five (range: zero to eight disorders). Between 1995 and 2005 most states added tests so that the average number of screening tests done by 2005 was 24 (Tarini et al., 2006). Today, there is a panel of 29 tests that has been recommended by the Department of Health and Human Services and has been adopted in all states (Kemper et al., 2014).

The expansion of newborn screening raises three problems. First, even the most accurate test has false positives. For rare conditions, the percentage of positive tests that are false positives is increased. Thus the more rare conditions that are added to a newborn screening panel, the more false positives there will be. False positives are associated with considerable parental anxiety and can lead to potentially dangerous and unnecessary diagnostic procedures or treatments. Second, expanded newborn screening costs money. Most of the cost is not for testing itself. Instead, it is for the follow-up counseling and testing after positive tests. Such follow-up is essential or the screening programs will not work. The Centers for Disease Control and Prevention (2008) has recently expressed concern about these costs. Finally, there is the potential for discrimination against patients for whom documented heterozygous carrier status conveys no recognized medical infirmity, but social or psychological stigma may be real. There is little funding available to assist or counsel these patients.

Recently, some centers have started to offer whole-genome sequencing (WGS) for newborns. Such testing raises all the issues

noted above for newborn screening. However, like newborn screening, it also offers the tantalizing prospect of better diagnosis leading to better treatment for some newborns whose conditions have been difficult to diagnose using more conventional methods. WGS is much more difficult to interpret than traditional newborn screening because every baby – and every adult – has many genetic variations of unknown significance.

Variants can only be interpreted after a good clinical history, family history, and physical examination have been performed. Data from these preliminary steps allow physicians to assess whether there are similar or related phenotypes in other family members; if so, the inheritance pattern can then be evaluated and assessed. Physical examination findings allow physicians to begin a search for potentially relevant genes. Mode of inheritance and a comprehensive phenotype can then be used to classify the patient's genomic variants. WGS may lead to the discovery of a known pathogenic variant, a novel pathogenic variant that is likely to be disease-causing, or a variant of unknown clinical significance in a gene known to cause human disease.

Clinical validity is a complicated and challenging aspect of WGS. Evidence is required to prove that a specific rare variant in a particular gene, detected by WGS, is indeed pathogenic and responsible for a particular clinical phenotype (Thiffault and Lantos, 2016).

Should Policy Dictate Resuscitation Practices?

Many professional societies in many countries have policies about resuscitation for babies born at the borderline of viability. Guillén et al. (2015) showed that among guidelines in 31 countries, 21 (68%) supported comfort care at 22 weeks' gestation and 20 (65%) supported active care at 25 weeks' gestation. Between 23 and 24 weeks' gestation, there was even greater variation.

These policies have practical effects. They lead to very different survival rates for seemingly similar babies in different countries. For example, in the Netherlands and Switzerland, survival at 25 weeks' gestation is as good as in the United States. Over 75% of infants born at 25 weeks' gestation will survive to discharge (Stoll et al., 2015). Before 25 weeks, however, outcomes in different countries vary widely. In the Netherlands and Switzerland, virtually no infant born at 24 weeks' gestation survives because there are policies not to provide intubation, resuscitation, or neonatal intensive care to such babies. (This has started to change at some centers in these countries – see, e.g., Morgillo et al., 2014.) By contrast, survival rates in the United States are 62% at 24 weeks' gestation and

37% at 23 weeks' gestation. Japan reports survival rates of 30% for babies born at 22 weeks' gestation and 70% for babies born at 23 weeks' gestation (Kusuda et al., 2006).

More interestingly, the policies shape the outcomes statistics that then become the evidence upon which future policies are based. It makes sense to not resuscitate babies if they have a 100% mortality rate. But, if they only have 100% mortality rate because they are not resuscitated, then the policies become a self-fulfilling prophecy.

Such policies may reflect a resources allocation decision. In the Netherlands, there is a limited budget and a communitarian ethic. There is a certain rationale behind spending money on all pregnant women, instead of 1% of micro-preemies. The United States appears ambivalent – we value individuals over community, are fascinated with high technology, and claim to prize our children. On the other hand, we will not spend money to prevent unwanted teen pregnancy, expand maternity leave, or provide visiting nurses for new mothers.

Finally, the concept of generational conflict must be considered. Many doctors appear to be quite comfortable calling delivery-room resuscitation of 24-weekers “optional,” based on GA alone (Janvier and Lantos, 2016). Given what we know about the factors other than GA that influence outcomes, this seems to be a curiously oversimplified approach to clinical decisions. It is not an approach that is used in other areas of medicine. For example, professional societies do not recommend the allocation of intensive care unit resources based on age alone. Such a practice might be called “discriminatory ageism.” However, with regard to premature babies, it ought, perhaps, to be considered equally discriminatory and labeled as “gestational ageism” (Wilkinson, 2012). Some suggest that the reason to limit such treatment is because it is too expensive, but studies show that it is remarkably cost-effective compared with the use of intensive care resources for elderly patients with respiratory failure (Lantos and Meadow, 2011). The relative cost-effectiveness of NICUs compared with medical intensive care units (MICUs) is based on the natural history of illnesses that lead to intensive care unit admissions. Most babies who are admitted to the NICU either die relatively quickly or survive. Thus most of the resources in NICUs are expended on patients who survive to leave the hospital. For adults, the opposite is true. With each passing day in the intensive care unit, the chances that an elderly patient will survive to leave the hospital go down. Thus a much higher percentage of the resources expended in adult intensive care units are used by patients who will not leave the hospital alive.

Summary

Ethical philosophy is a place to start, not a place to finish. Data are relatively easy to acquire and agree on. Policy is intriguingly insensitive to data, but that may reflect social and political realities that exist beyond the NICU – perceptions of disability, abortion

politics, individual versus communitarian emphasis, fascination with technology, discrimination, publicity, financial constraints – so that an ethical course of action in one country, one city, or one family might seem perverse elsewhere.

Global Neonatal Health

CYRIL ENGMANN AND MANEESH BATRA

KEY POINTS

- In many parts of the world, childbirth remains a risky, life-threatening process.
- Over the past 25 years, decreases in neonatal mortality rates (NMRs) have been slower than those for maternal and child mortality.
- Intrapartum birth asphyxia, sepsis, and prematurity are the most common causes of global neonatal mortality.
- Lower NMRs are strongly associated with increased gross national income, decreased total fertility rates, higher female literacy, at least one antenatal care visit, presence of a skilled attendance at birth, and a higher percentage of birth registrations.

Global Newborn Health – History

It is essential for all those who work with mothers and their babies to understand the global health milieu and the historical factors that have shaped the field as it stands today. More importantly, as neonatologists look to the future, a contextualizing of their work in neonatal and perinatal health and an appreciation of what levers need to be pulled to affect the future of the world's newborns become even more important. Finally, for those who want to influence these processes and contribute to moving the field forward, a deeper understanding becomes necessary (Darmstadt et al., 2014). Today more than ever, the field of global newborn health is much broader and quite distinct from the technologically infused might of neonatal intensive care units (NICUs) in high-income countries. This chapter will discuss the policies, programs, research, advocacy, and common underlying public health themes that affect the newborn globally (Lawn et al., 2014). Armed with this knowledge, the healthcare provider working with mothers and newborns in today's multicultural environments will be better able to understand and provide the culturally and contextually sensitive care necessary to be effective and will have the tools to springboard the future of global newborn health (Engmann, 2011; Engmann et al., 2013a).

Childbirth is a risky, life-threatening process with good maternal and neonatal outcomes far from assured. It is therefore no surprise that newborns have been given special attention (either because they lived, died, or were maimed during birth) throughout history. Some of the earliest recordings of newborns in ancient history date back to the second century AD and are ascribed to the Greek physician and gynecologist Soranus of Ephesus (Dunn, 1995). Other artists from late antiquity and the middle ages depict the

process of childbirth with a mother in the squatting position, a doula/helpmate supporting her, a midwife, and perhaps in the most important role, someone praying, invoking all the extra help possible from the deities (Fig. 4.1).

The *Boke of Chyldren*, written by Thomas Phaïre in 1545, was one of the earliest books published in English (Phaïre, 1545) while the 17th century treatise by William Harvey remains among the most elegant descriptions of the transition from fetal to extrauterine life (Dunn, 1990). The Talmud and the Old Testament are replete with stories concerning babies. For example, one story describes the birth and early life of Moses, who at 3 months of age was placed in a basket, floated down the River Nile, and subsequently adopted by the Pharaoh's daughter. Another story, perhaps one of the earliest recorded cases of sudden infant death syndrome and baby-snatching, describes two women each with newborn babies who live in the same house. One baby dies in the night, and its mother is accused by the other of waking up and switching her dead baby with the live one. This dispute is brought to King Solomon for adjudication. He recommends that the baby be sawn in two with one-half given to each woman. One woman, the mother of the dead baby, agrees to this proposal, while the mother of the live baby, appalled that her baby will be killed, says its life should be spared and agrees to relinquish her claim to being the mother. This act convinces King Solomon that she is the rightful mother, and he adjudicates the baby should be given to her (Bible: 1 Kings 3:16–28). By AD 315, the Roman Empire had established laws supporting the enslavement of “foundlings” or abandoned babies, in a bid to counter a faltering population growth and infanticide and to promote the adoption or child-rearing of orphans (Spaulding and Welch, 1991). During the 17th century a number of countries started to build “Foundling Hospitals” and by the late 19th century, preterm babies, known as “hatchlings,” were an important draw at exhibitions and public fairs where they were displayed as they lay in incubators known as “hatcheries” (Silverman, 1979).

Various societies have evolved cultural practices such as delayed naming of a child, perhaps in response to high perinatal and neonatal mortality rates (NMRs). In certain Asian cultures, full naming ceremonies are not held until the infant is several months old, while in Jewish tradition, full mourning for the entire year is not required for a neonatal death (Ginzberg et al., 2003). In some African populations, the mother and her newborn baby are not allowed to be seen for the first 7 days after birth except by very close family and friends to ensure the “evil eye” is not put on either the mother or her baby. In other settings, a “naming ceremony”

• **Fig. 4.1** Classical Greek Image of Woman Giving Birth, Depicting Doulas, Midwife, and a Woman Praying for the Safety of Mother and Baby. (From <http://visualizingbirth.org/classical-greek-image-of-woman-giving-birth>.)

where a baby is provided a name and then publicly introduced to the community does not occur for the first 7 days or sometimes longer. This is to ensure that the baby has decided to stay on earth and thus differentiated itself from being a “spirit child” who will die (Denham et al., 2010). To counter the death of a baby in the family, certain societies in Africa and Asia give the next child a coarse or earthy name to ward away spirits who might otherwise also take the new arrival.

Early in the 20th century, an obstetrician advocated in the *British Medical Journal* for the specialized training of doctors and nurses in neonatal medicine and for the construction of specialized newborn health facilities. He went on to predict that within a short period of time, the specialist in neonatal diseases and the nurse intensively trained and expert in the management of the delicate newborn would be commonplace (Ballantyne, 1923). By the mid-20th century, there was a deepening realization among certain pediatric groups, boards, and societies that the study and practice of pediatrics during the first month of life were distinct and specialized enough to require further training. Furthermore, the need for an in-depth understanding of embryonic, fetal, and neonatal pathophysiologic processes, the role of technology, including ventilators, and the complexities of the medical management of a sick baby led to the creation of neonatology as a distinct subspecialty in the United States. A subboard of the American Board of Pediatrics was created to oversee and shape the current and future knowledge and understanding of the field. The first subboard examination in neonatal–perinatal medicine was offered in 1975 (Philip, 2005).

By the close of the 20th century, there was emerging appreciation in global health policy and programmatic circles that the newborn period provided unusual challenges, with drivers influencing survival that were different to the more traditional child health programs. Another realization was that the newborn was absent from maternal and child health programs. This was because national and international maternal health programs had hitherto assumed that child health programs encompassed close attention to newborn care as newborns grow to become children, while child health programs, believing the mother and neonate to be inextricably linked at

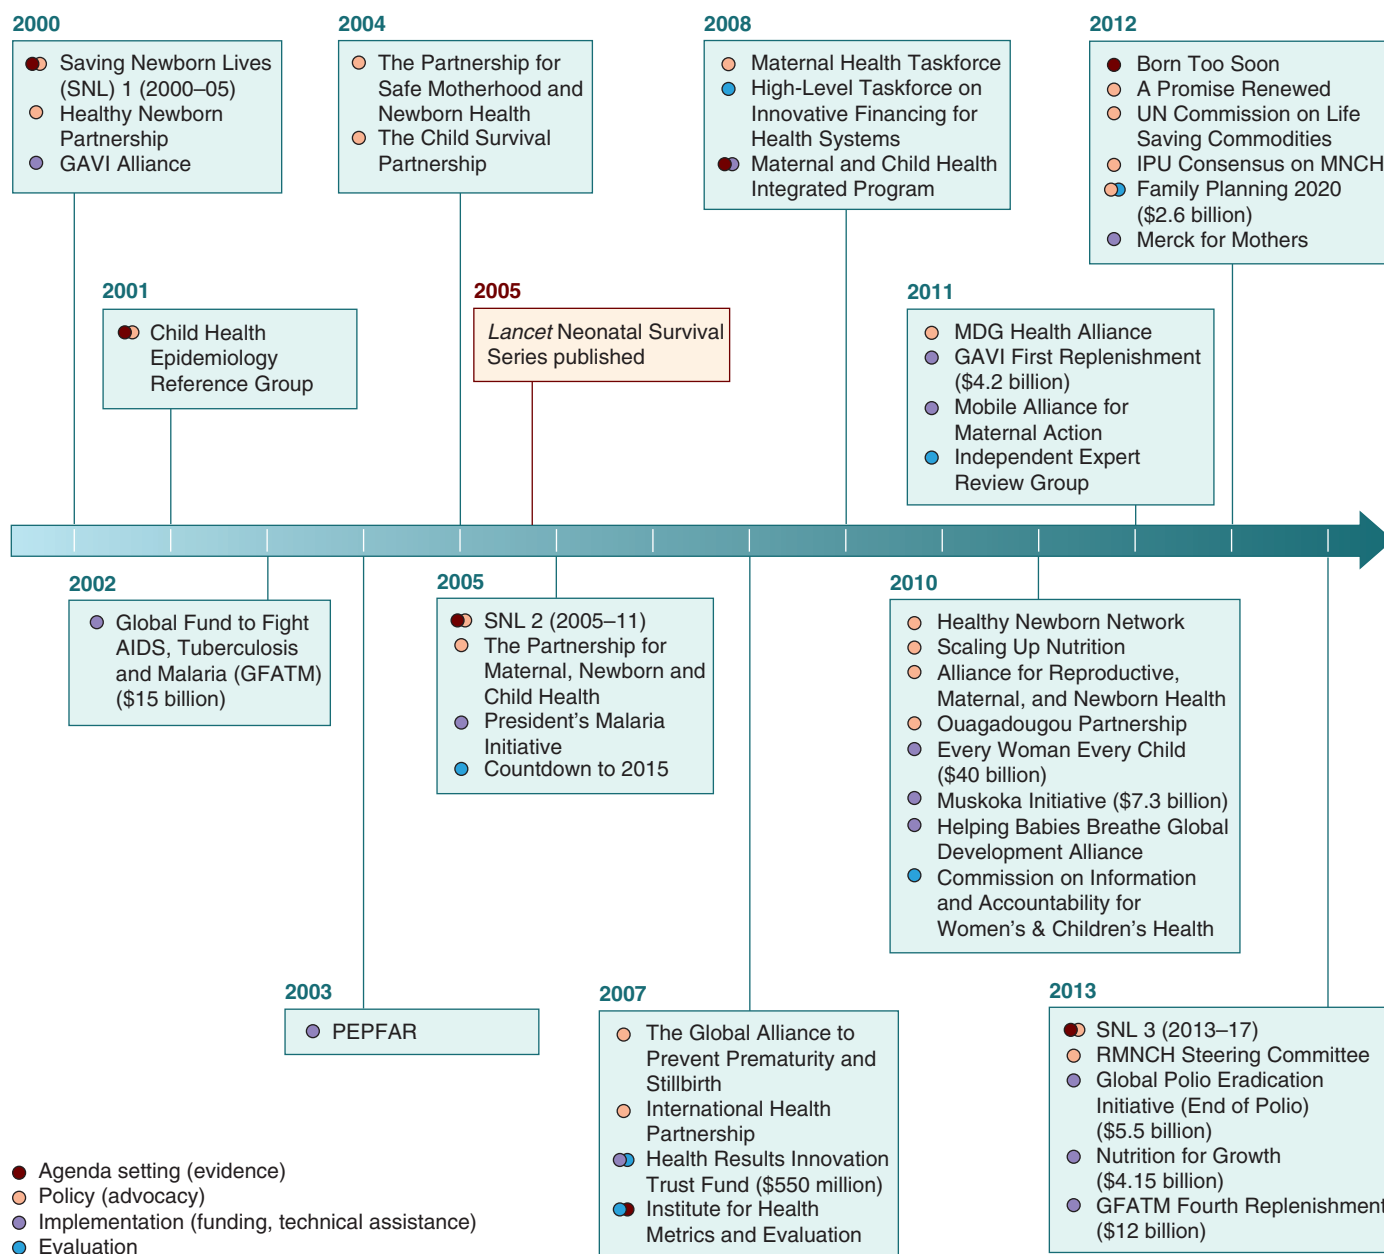

birth, had subsequently assumed that maternal programs included a strong focus on the neonate (Tinker et al., 2010). As a result, there was a paucity of routine newborn surveillance and epidemiologic data collected globally and nationally (The World Health Report, 2005). Programmers, policymakers, and funders started increasing their focus on the neonate. Abhay Bang and colleagues from the Gadchiroli district of India published a landmark series on the effects of a home-based newborn care program and compared these against control village clusters who had no intervention. The program involved a package of interventions that included training of village health workers in neonatal care who then made home visits and managed birth asphyxia, premature birth or low birth weight, hypothermia, breastfeeding problems, and neonatal sepsis (septicemia, meningitis, and pneumonia). In addition, assistance by trained traditional attendants, a health promotion program, and fortnightly supervisory visits were provided. The authors reported a decline in NMR from 62 to 25 per 1000 live births in the intervention clusters, whereas in control clusters, they reported an *increase* in NMRs from 58 to 64 per 1000 live births (Bang et al., 2005).

In 2000, the Bill and Melinda Gates Foundation provided funding to the nongovernmental organization (NGO) Save the Children in order to create a special entity called “Saving Newborn Lives.” This group’s remit was to focus and harness newborn stakeholder energies on moving the global newborn agenda forward through research and program work, which would inform advocacy and policy (Tinker et al., 2010). Soon afterwards, Black and colleagues published a child survival series with the first paper provocatively titled “Where and why are 10 million children dying every year?” (Black et al., 2003). This was followed by another seminal publication from the *Lancet* Neonatal Series – which asked “4 million neonatal deaths: When? Where? Why?” (Lawn et al., 2005). These publications highlighted the following: (1) sepsis, intrapartum birth asphyxia, and prematurity were the major drivers of 4 million newborn deaths; (2) most neonatal births and deaths were occurring in low- and middle-income countries, outside of healthcare facilities, and in the home; and (3) there was an absence of district, regional, national, or global data on newborn survival. These seminal papers and the strong advocacy by a handful of newborn champions spurred national governments, United Nations (UN) agencies, NGOs, academic institutions, funding agencies, and other newborn stakeholders to begin developing programs, policies, and research agendas that were newborn focused (Martines et al., 2005) (Fig. 4.2).

Global Newborn Health 2000–2015: Addressing Cause-Specific Neonatal Mortality

Coinciding with increased understanding from seminal publications and with the support of newborn champions, the turn of the 21st century heralded the launch of the Millennium Development Goals (MDGs) (Fig. 4.3).

The MDGs were seen as a focusing and galvanizing effort through which the global community would channel its collective resources and efforts to address major global development issues (*The Millennium Development Goals Report 2015*, 2015). The goals, set in 2000, included eradicating extreme poverty and hunger, achieving universal education, promoting gender equality and empowerment of women, reducing child mortality (death in children under the

• **Fig. 4.2** Key Stakeholders, Events, and Timeline Pertaining to Global Newborn Health From January 2000 to December 2013. *AIDS*, Acquired immunodeficiency syndrome; *GAVI*, Global Alliance for Vaccines and Immunization; *IPU*, Inter-Parliamentary Union; *MDG*, millennium development goals; *MNCH*, maternal, newborn, and child health; *PEPFAR*, President's Emergency Plan for AIDS Relief; *RMNCH*, reproductive, maternal, newborn, and child health and nutrition; *SNL*, Saving Newborn Lives; *UN*, United Nations. (From Darmstadt GL, Kinney MV, Chopra M, et al. Who has been caring for the baby? *Lancet*. 2014;384(9938):179.)

age of 5 years) by two-thirds, reducing maternal mortality by three-quarters, combating HIV/AIDS, malaria, and other diseases, ensuring environmental sustainability, and establishing global partnerships for development (*United Nations Millennium Declaration, Resolution Adopted by the General Assembly*, 2000).

Although these ambitious goals were not all reached by the target date of 2015, the MDG era has arguably seen the greatest improvements in health and development indicators in the history of humankind (*The Millennium Development Goals Report 2015*, 2015). For example, the number of people living in extreme poverty has decreased from 1.9 billion to 836 million; maternal and child mortality have been halved; net school enrolment has reached

91% with sub-Saharan Africa seeing a 20% increase in average literacy rates of women; and in Southern Asia the number of girls enrolled for every 100 boys had increased from 70 to 103 by 2015. Approximately 91% of the world's population is now using improved drinking water sources, compared to 70% in 1990 (*The Millennium Development Goals Report 2015*, 2015).

One of the main themes that the various newborn publications articulated was that most newborn births, and 99% of newborn deaths, occurred in community-based settings such as the home and not in hospitals and health facilities (Lawn et al., 2005; Darmstadt et al., 2009). Furthermore, country case studies showed that a handful of low- and middle-income countries had seen

The Millennium Development Goals (MDGs) are a set of global development objectives to be achieved by 2015 that were unanimously adopted at the United Nations Millennium Summit in September 2000. Attainment of the eight individual goals is to be measured by progress against 18 associated targets.

impressive reductions in national NMRs *before* the creation of the first neonatal intensive units in the country. Sri Lanka, for example, had experienced reductions in mortality from over 50 deaths per 1000 live births in the 1950s to less than 20 deaths per 1000 live births by 1985 when the first NICU in the country was developed (Martines et al., 2005). The Indian state of Kerala also had seen similar impressive reductions in neonatal mortality. Further analysis suggested that in both Sri Lanka and Kerala, sustained inputs and utilization of primary care and government facilities had played major roles in the decrease in their NMRs, not the introduction

of NICUs. In Sri Lanka, for example, by 1996 there was a midwife to patient ratio of 1:3000–5000, close to 100% antenatal care coverage, and an 86% facility-based delivery rate. There was no charge to women for their medical care and the average distance from home to a health facility was 1.4 kilometers, with 5 kilometers being the furthest distance of advanced hospitals from those health facilities. Higher maternal educational levels, effective antenatal care provision, and higher contraception prevalence rates were perceived to have contributed significantly to these impressive reductions in NMRs (Lawn et al., 2005).

Thus the prevailing approaches of most newborn stakeholders came to focus primarily outside formal health facilities, since that was where the burden of births and newborn deaths occurred. In contrast with other MDG indicators, including child and maternal mortality that halved between 1990 and 2015, newborn mortality has not achieved the same degree of success. Global NMRs decreased by 37%, from 33 to 21 deaths per 1000, representing a decrease in number of newborn deaths from 4.4 million in 1990 to 2.9 million in 2014 (Lawn et al., 2014). As a result, as child mortality has fallen, the proportion of childhood deaths attributable to neonatal mortality is *increasing* (Lawn et al., 2014 citing [Levels and Trends in Child Mortality Report 2013, 2013]). There is also wide variation in NMRs, absolute neonatal deaths per year, and in annual rates of reduction for all regions of the world, except for high-income countries. Asia has the largest absolute number of neonatal deaths when the top 10 countries with highest neonatal deaths in the world are considered. However, where NMRs are considered, Africa contributes 8 out of the 9 countries with the highest NMRs (Fig. 4.4).

Throughout history, verbal autopsy (VA) has been a commonly used technique to determine neonatal cause of death in settings without strong health systems. Estimates are that virtually every low- and middle-income country uses some aspect of VA for its vital registration activities (Black et al., 2010). VA involves the administration of a systematic, structured questionnaire to the primary caregiver (usually the mother) of the deceased, in this case the baby, by trained questioners. During this process, the signs, symptoms, and circumstances surrounding the death are ascertained. Afterwards, a panel, typically consisting of two or three physicians, individually codes and assigns a cause of death, which is sometimes based on an a priori agreed-upon algorithm (Fottrell and Byass, 2010). When there are discrepancies in assignment of cause of death, the physicians come together to discuss and reach a final agreement (Engmann et al., 2011a). Many studies have been conducted to compare the results of these community-based VA assignments of cause of death to hospital-based assignments, and the results have been favorable for the VA (Engmann et al., 2011a).

• **Fig. 4.4** Variation between countries in neonatal mortality in 2012 (A) and variation in average annual rates of reduction of neonatal mortality rate for all regions apart from developed regions (1990–2012), showing the fastest progressing country according to Millennium Development Goal region (B). Data from UN Interagency Group for Child Mortality Estimation estimates for NMR in 1990–2012. NMR, neonatal mortality rate per 1000 live births; NMR ARR, 1990–2012 average annual rate of reduction in neonatal mortality rate, based on calculation. (From Lawn JE, Blencowe H, Oza S, You D, et al. Every Newborn: progress, priorities, and potential beyond survival, *Lancet*. 2014; 384:189–205. Copyright 2014.)

There are many variations of the execution of VA. Some authors have examined the optimal use of VA interviewers, others the use of VA coders, and others algorithms and neural networks that may help to determine cause of death (Byass et al., 2015). Investigators from the Eunice Kennedy Shriver National Institute of Child Health and Human Development's Global Network for Women and Children's Health probed the technique of perinatal VA to assess the correlation of single versus multiple VA coders, non-physicians versus physicians in assigning cause of death, and the use of birth attendants as VA respondents (Engmann et al., 2009, 2011a, 2011b). After a training period, individual physicians made determinations of cause of stillbirth and early neonatal death that were comparable to physician panels, and non-physician respondents had cognitive and applied knowledge scores comparable to physician panels. Perhaps most promising and with strong programmatic potential, birth attendant responses (when compared to those of primary caregivers of the deceased) showed strong concordance across all questions on early neonatal deaths (94%) and stillbirth (93%) (Engmann et al., 2012b). For as long as there remains a large number of newborn births and deaths that occur outside of formal or weak health systems, VA is likely to be one of the most commonly used methods to inform global, national, and regional programs and policies and to conduct research activities.

Major Causes of Neonatal Mortality

Birth Asphyxia

Birth asphyxia is defined by the World Health Organization (WHO) as the failure to initiate and sustain spontaneous breathing at the time of birth. More recently, there have been calls for more precision in terminology that is focused on marking the timing of the insults such as antepartum, intrapartum, and postpartum asphyxia (de Bernis et al., 2016). Of the 136 million babies born every year, approximately 10% require some form of resuscitation at birth (Kattwinkel et al., 2011). Approximately 14 million of these babies will require only stimulation at birth to establish regular respirations, while approximately 4 million will require stimulation plus basic resuscitation with a self-inflating resuscitation bag and mask and some postresuscitative care. Unfortunately, a further 700,000 newborn babies die from intrapartum-related conditions. A variety of research studies have focused on improving newborn resuscitation skills (Carlo et al., 2010a, 2010b; Wall et al., 2010; Lee et al., 2011; Pasha et al., 2013; Bang et al., 2014). The large, multicenter FIRST BREATH trial—conducted in the Democratic Republic of the Congo, Zambia, Guatemala, Pakistan, India, and Argentina and involving over 50,000 babies—reported a one-third reduction in perinatal deaths after a newborn resuscitation program was instituted. Curiously, the majority of this reduction was in stillbirths. The authors concluded that improved resuscitation skills also reduced the amount of misclassification between stillbirths and early neonatal deaths (Carlo et al., 2010a).

A number of studies have examined the skill level of healthcare providers and the ability of resuscitation training programs to improve resuscitation skills. In one study of resuscitation training conducted among nurses, midwives, nurse anesthetists, and physicians in Ghana, West Africa, nurses had the lowest scores for effective resuscitation prior to training; however, afterwards their scores nearly doubled and in some cases exceeded those of physicians. (Enweronu-Laryea et al., 2009). More recently, the Helping Babies Breathe (HBB) program was developed by the American Academy of Pediatrics. HBB focuses on resuscitation in low- and middle-income settings and emphasizes the first “golden minute.” An

evaluation of this program in India and Tanzania suggested a significant reduction in neonatal deaths (0.53 relative risk [RR], 95 confidence interval [CI] 0.43–0.65) and intrapartum stillbirth rates (0.76 RR, 95% CI 0.64–0.9) (Msemo et al., 2013). As with most research trials, it remains to be seen whether incorporation of HBB into national and regional programs will result in similarly impressive gains.

There is increasing appreciation that in order for a program to be successful, it requires a functioning healthcare system and incorporation of all elements across the continuum of care, including recognition of danger signs (Aborigo et al., 2014). This has led a number of authors to adapt the “three delays” conceptual model proposed for maternal health to newborn health. This model comprises (1) delay in recognition of illness in the home, (2) delay in transportation from home to facility, and (3) delay in appropriate and effective management at the facility (Waiswa et al., 2010; Engmann et al., 2013a). At the policy level, it is imperative that global and national policies exist for the management of intrapartum birth asphyxia and that funding mechanisms are in place to support implementation. Currently one pernicious challenge in many low-income settings where standard neonatal resuscitative practices are absent or weak is that well-meaning international groups of neonatal experts teach a variety of neonatal resuscitation programs, sometimes several different programs within the same hospital. Thus standardization and mastery of practice of one method or program are absent, and overall goals of improving resuscitation skills are not efficiently met. A solution might be for the countries or hospitals involved to agree on one standard program, ensure mastery, and make that the standard of care. Another challenge is that nursing staff that are trained in resuscitation programs are frequently transferred from obstetric and newborn units to other parts of a hospital, which further limits practice and expertise in optimal neonatal resuscitative practices. Recognizing this, many facilities are beginning to change their policies and procedures such that staff trained in neonatal resuscitation remain in one department to ensure opportunities to practice and apply their learnings.

Neonatal Sepsis

Neonatal sepsis has long been one of the major causes of newborn morbidity and mortality, and over the past decade there have been a large number of research and program approaches to this problem (Ganatra and Zaidi, 2010; Seale et al., 2014). Box 4.1 outlines the common research and programming directions undertaken to decrease global neonatal sepsis rates over the past decade.

While the gold standard for treatment of presumed serious bacterial infections in high-income settings is parenteral antibiotic therapy delivered in a health facility, evidence suggests that non-medical providers can decrease mortality from neonatal infections in community settings, by using specific tools to guide the assessment, management, and referral process (Ganatra and Zaidi, 2010; Baqui et al., 2015). Examples of successful community-based intervention trials for sepsis include the Society for Education, Action, and Research in Community Health (SEARCH) trial in India where the sepsis-specific NMR decreased by 90% after the intervention (Bang et al., 2005) and the Projahnmo Study Group trial in Bangladesh where overall NMR declined by 34% (Baqui et al., 2008). In 2015, several trials of simplified antibiotic regimens for neonatal sepsis were published. This cluster of studies conducted in the Democratic Republic of Congo, Nigeria, and Kenya, and similar trials in Bangladesh and Pakistan, all showed that simplified antibiotic regimens for serious bacterial infections showed

• BOX 4.1 Common Research and Programming Directions to Decrease Global Neonatal Sepsis Rates

- Clean delivery kits
- Recognition of danger signs of neonatal sepsis
- Strength of association of different signs and symptoms in the community-based management of severe sepsis through the infant and young child study
- Prevention of neonatal sepsis
- Responsible bacteria for presumed serious bacterial sepsis
- Treatment of neonatal sepsis in both community and facility settings
- Chlorhexidine application to the umbilical cord, the entire baby, and the vagina

Data from Ganatra HA, Zaidi AK. Neonatal infections in the developing world, *Semin Perinatol.* 2010; 34: 416–425, Edmond K, Zaidi A. New approaches to preventing, diagnosing, and treating neonatal sepsis, *PLoS Med.* 2010; 7, pp. e1000213. doi: 10.1371/journal.pmed.1000213, Sinha A, Sazawal S, Pradhan A, Ramji S, Opiyo N. Chlorhexidine skin or cord care for prevention of mortality and infections in neonates, *Cochrane Database Syst Rev.* 2015; 3: doi: 10.1002/14651858.CD007835.pub2

noninferiority when compared to the WHO-recommended standard of care (at least 7–10 days' worth of parenteral antibiotics, at least twice a day) ([African Neonatal Sepsis Trial – AFRINEST, 2015](#)).

Similarly, many studies have examined the use of chlorhexidine for preventing and reducing omphalitis/sepsis-specific neonatal mortality. Cleaning the vagina with chlorhexidine, wiping the entire baby, and cleaning the cord are three approaches that have been investigated ([Sinha et al., 2015](#)). While vaginal wipes and cleaning the entire baby resulted in modest differences in neonatal mortality, more recent metaanalyses suggest that 4% chlorhexidine used to clean the umbilical cord results in overall reductions in NMRs of up to 12% ([Sinha et al., 2015](#)).

At the policy level, the rate of publication of these studies has, in some cases, outrun global policymakers. Currently, the WHO recommends daily application of 7.1% chlorhexidine to the umbilical stump of babies who are born at home in high neonatal mortality settings (greater than 30 deaths per 1000 live births). However, since these recommendations were made based on the available evidence, and since there are a number of more recent studies nearing completion, these recommendations will likely be modified.

There have been some policy breakthroughs in neonatal sepsis management at global and national levels that are worth noting. For example, in India, auxiliary nurse midwives are now allowed to administer injectable antibiotics, and similarly, in Ethiopia, community health workers are now able to provide community management of neonatal sepsis. At the global level, policy groups have also accelerated the speed of policy process-making, and thus there are now clear and timely policy recommendations by the WHO for the use of simplified regimens. These developments have paved the way for program implementation by governments, private practitioners, and other stakeholders and appear poised to contribute to future reductions in sepsis-specific neonatal mortality.

A highly successful approach to the prevention of neonatal sepsis in high-income countries has been the development and implementation of strategies aimed at reducing maternal colonization with group B streptococcus (GBS). In these settings, early-onset GBS disease was a leading cause of neonatal infections, and high maternal colonization rates were contributory. Given the successes of risk-screening and screening-culture based identification of

women whose newborns may benefit from intrapartum antibiotic prophylaxis, one might expect that similar approaches in resource-limited settings may also be effective in reducing early-onset neonatal infections. However, it appears that the causative microbiologic agents in neonatal sepsis in Africa and Asia are quite different from those in North America and Europe. [Table 4.1](#) outlines the causative agents of sepsis in young infants up to 90 days of age in low- and middle-income countries, by age of onset. Although large-scale population-based data on maternal colonization and etiologies of neonatal sepsis do not exist, there have been several reports of causative agents identified through robust culture methods from health facilities in low-income settings. In a recent review, Gram-negative organisms accounted for twice the number of neonatal infections as those caused by all gram-positive organisms (including GBS) ([Zaidi et al., 2009](#)). Because the efficacy of GBS prophylaxis programs in low-income countries have yet to be widely and rigorously evaluated, it will be premature to promote the practice of GBS prophylaxis in such settings.

Preterm Birth

In 2012, over 100 stakeholders from the global newborn community including representation from high, middle, and low-income countries aligned efforts to design, develop, and disseminate the World Prematurity Report, which outlined more precisely than ever before the burden of newborn mortality attributable to prematurity (*Born Too Soon: The Global Action Report on Preterm Birth, 2012*). Estimates are that 15 million babies annually are born preterm, and one million of these babies die from direct preterm birth complications, making this the most common cause of neonatal mortality. Of cause-specific neonatal mortality, the smallest reductions have occurred for preterm birth complications (<20%) globally; thus the authors state, “addressing preterm birth is fundamental to acceleration of NMR reduction” ([Lawn et al., 2014](#)). Preterm rates are rising in most countries, and 85% of these births are between 32 and 36 weeks. The top 10 countries with the highest numbers of premature babies born each year are India, China, Nigeria, Pakistan, Indonesia, United States, Bangladesh, Philippines, Democratic Republic of Congo, and Brazil. While *prevention* of premature delivery by a mother remains somewhat elusive and continues to attract ongoing research attention primarily in high-income countries, *management* of premature babies in all settings, particularly low- and middle-income countries, has received increasing attention over the past 15 years. An overarching challenge and opportunity around the area of prematurity remain a coordinated response by funders, policymakers, researchers, and programmers to systematically address the entire field. To begin this process, a consortium of researchers and funders has proposed a “preterm solution pathway” that maps out the discovery, development, and delivery elements of preterm birth with the prediction, prevention, and clinical care management functions, as a blueprint for this effort ([Lackritz et al., 2013](#)). It is instructive to consider some of the issues that arise in the execution of the following preterm management modalities.

Antenatal Corticosteroids

Liggins and Howie published their seminal work on antenatal corticosteroids in 1972, and, since then, widespread use in health facilities in high-income countries has resulted in marked reductions in the NMR ([Liggins and Howie, 1972](#); [Roberts et al., 2006](#); [Mwansa-Kambafwile et al., 2010](#)). Recently, Althabe and colleagues from the National Institute of Child Health and Human

^bIncludes infants 29–60 days of age.

From Zaidi AK, Thaver D, Ali SA, Khan TA. Pathogens associated with sepsis in newborns and young infants in developing countries, *Pediatr Infect Dis J*. 2009; 28: S10–18.

Developments Global Network sought to assess the feasibility, effectiveness, and safety of a population-based, multifaceted strategy to implement antenatal treatment of women at risk of preterm labor with corticosteroids compared with standard of care, on neonatal mortality attributable to preterm birth in low- and middle-income settings (Althabe et al., 2015). In this 18-month, cluster-randomized trial conducted in rural and semi-urban clusters within six countries (Argentina, Guatemala, India, Kenya, Pakistan, and Zambia), 28-day neonatal mortality among newborns whose birthweight was less than the 5th percentile (as a proxy for preterm birth) was examined. There were 47,394 live births, with 2520

(5%) less than the 5th percentile for birthweight in the intervention clusters and 50,743 live births and 2258 (4%) less than the 5th percentile who completed follow-up. A total of 2361 women in the intervention group received steroids compared to 215 women in the control group ($P < .001$). Among those less-than-5th-percentile infants, 28-day mortality was 225 per 1000 live births for the intervention group and 232 per 1000 live births for the control group. Among the entire population, 28-day mortality was 27.4 per 1000 live births in the intervention group and 23.9 in the control group (RR 1.12, 1.02–1.22; $P = .0127$). Suspected maternal infection was reported in 1207 (3%) of the intervention

group of women and 2% of the control group with an odds ratio (OR) 1.45, 1.33–1.58, $P < .0001$. The authors concluded that despite increased use of antenatal corticosteroids in low birth weight infants in the intervention group, neonatal mortality increased in the population as a whole: for every 1000 women exposed in this strategy, an excess of 3.5 neonatal deaths occurred, and the risk of maternal sepsis seemed to have increased (Althabe et al., 2015).

Azad and Costello reflected on these results and recommended three questions that should be answered before roll-out of modalities in low- and middle-income countries occurs:

1. Is there biologic plausibility? Does the modality *work* in mothers and infants in poor populations, for which there is limited care available? (For example, in this study there were few level two or intermediate neonatal centers.)
2. Do safety issues exist such that if the modality is applied at scale, in this case with corticosteroids, will there be no significant increase in maternal sepsis, perinatal death, or childhood disability?
3. Is there any evidence of benefit for the great majority of preterm infants born at more than 33 weeks?

Clearly these questions need to be considered carefully a priori, before rolling out any corticosteroid interventions (Azad and Costello, 2014).

Continuous Positive Airway Pressure

In high-income settings, continuous positive airway pressure (CPAP) has long been used as a treatment modality for respiratory distress syndrome, and many studies have shown a decrease in preterm-specific neonatal mortality. Feasibility of CPAP, particularly bubble CPAP, is increasingly being reported from single sites in various countries, including Malawi, Uganda, India, and Bangladesh (van den Heuvel et al., 2011; Brown et al., 2013; Daga et al., 2014; Chisti et al., 2015; McAdams et al., 2015). Although CPAP continues to enjoy widespread use and development, it is only recently that a systematic review examined its safety in low- and middle-income settings (Martin et al., 2014). When compared to oxygen therapy followed by mechanical ventilation if needed, the authors reported a 30%–50% decrease in need for mechanical ventilation. They concluded that bubble CPAP is safe and reduces the need for mechanical ventilation, although they recommended further research into the efficacy of bubble CPAP in low- and middle-income settings. Recent efforts are focused on building and testing different CPAP devices in order to find one that is efficient, durable, affordable, and sustainable in low-income settings. Investigators at Rice University, Houston, TX, Program for Appropriate Technology in Health (PATH), University of Washington, Seattle, WA, and Seattle Children's Hospital, Seattle, WA, are among those working closely with colleagues in countries such as Malawi, Uganda, and Kenya. Other organizations such as the *East Meets West Foundation* have a programmatic focus that develops invasive and noninvasive low-cost, custom-designed, durable equipment including ventilators and CPAP machines that are deployed primarily in Asia at present. A notable feature of this latter program is that it provides equipment maintenance, timely repairs, and support – both on site and remotely.

Surfactant

The widespread use of this treatment to reduce surface tension of the alveoli, especially in respiratory distress syndrome, is well known. However, the cost of implementing widespread use in low- and

middle-income settings has thus far been prohibitive. With a single treatment cost ranging from US\$450–900 in US hospitals, surfactant remains prohibitively expensive in resource-constrained countries and is thus only occasionally seen in the private sector, where patients must purchase it themselves. While there has been interest in developing cheaper alternatives, this has not materialized into tangible outcomes.

Kangaroo Mother Care

Kangaroo mother care (KMC) is defined as skin-to-skin care, exclusive breastfeeding, supportive care of the mother–baby unit, and close follow-up after discharge (Lawn et al., 2011; Engmann et al., 2013b). This technique was first described in Colombia in the 1970s and was designed to combat the phenomenon of NICU overcrowding. KMC has been shown to have multiple benefits for preterm infants. One analysis estimated that up to 450,000 preterm deaths could be averted each year if near-universal coverage is instituted (Lawn et al., 2010). There are many additional benefits of KMC, including strengthened immunity for the baby, increased psychological benefits, longer-term neurodevelopmental benefits, and low cost. Yet, global uptake of this practice has been very poor, estimated in 2013 to be less than 5%. Reasons postulated for this include:

1. KMC is seen as a poor-persons practice, only to be utilized as a next-best alternative.
2. Many healthcare workers either do not know about or believe in the benefits of KMC and lack skills necessary for successful implementation.
3. Cultural and social norms related to the mother and newborn practices make uptake of KMC challenging.
4. Human resources necessary for the effective implementation of KMC are missing and the role of mothers and communities has been overlooked.
5. KMC has not been included in many country-level government newborn agendas. (Engmann et al., 2013b).

A systematic review of barriers and enablers of KMC practice found that four of the top five ranked barriers were resource related, and all ranked above low awareness of KMC. Thus issues with the facility environment/resources, negative impressions of staff attitudes or interactions, lack of help with KMC practice, other obligations, and low awareness of KMC infant health are significant barriers. Top enablers included “mother–infant attachment” and support from mothers, families, friends, and mentors. The authors conclude that since KMC implementation is so context-specific, it is critical that focused ethnographic and qualitative research need to be done, while at the same time, the effectiveness of various user-centric designs for promoting KMC and ensuring support for the mother must be studied (Seidman et al., 2015). A global KMC Acceleration Group has recently been formed to help drive this agenda (Vesel et al., 2015).

Global Newborn Health at the End of the Millennium Development Goals Era

The newborn is at the nexus of many intersections across the health sectors, and numerous newborn-sensitive and newborn-specific facets affect morbidity and mortality. The conceptual framework for interventions to improve the health of every mother and newborn, as described by Bhutta and colleagues, is useful to consider (Fig. 4.5). With many of these interventions, improvements in

| | Preconception nutrition care | Antenatal care | Care during labor and childbirth including complications | Immediate newborn care | Care of the healthy neonate | Care of the small and ill neonate |
|--|------------------------------|------------------------------|--|------------------------------|-----------------------------|-----------------------------------|
| Estimated maternal lives saved by 2025 | 0 | 7500 (6700–9100) | 150,000 (137,100–158,900) | NA | NA | NA |
| Estimated stillbirths prevented by 2025 | 23,000 (17,800–26,500) | 240,000 (150,800–374,500) | 550,000 (432,500–531,400) | NA | NA | NA |
| Estimated neonatal lives saved by 2025 | 110,000 (111,800–118,300) | 43,000 (36,500–46,900) | 790,000 (588,500–865,000) | 190,000 (136,300–280,400) | 230,000 (64,300–261,500) | 580,000 (531,000–621,000) |

• **Fig. 4.6** Estimated Effect of the Intervention Packages on Numbers of Neonatal Lives Saved and Costs According to Levels of Care by the Year 2025. Error bars represent ranges. NA, not applicable; NMR, neonatal mortality rate.

Understanding the milieu, the knowledge, attitudes, beliefs, and interpretations of families and communities is a critical first step in any intervention design (Moyer et al., 2014). It is also important for individualized care of the patient, especially for care occurring in the home. This perspective has led to the development of a technique known as social autopsy at the community level. Social autopsy provides the rich contextual tapestry of social factors that frames the biomedical model of the VA (Kallander et al., 2011).

The end of the MDG period saw the launch of a coordinated global effort involving all 194 countries signatory to the UN that was entitled “Every Newborn: An Action Plan to End Preventable Deaths.” Box 4.2 outlines the vision, targets, goals, and strategies of the Every Newborn Action Plan. This effort brought together a large array of countries and their newborn stakeholders, including

Ministries of Health and Finance, academics, programmers, NGOs, funders, policymakers, clinicians, and, most importantly, civil society groups (*Every Newborn: An Action Plan to End Preventable Death*, 2016). A key differentiator of this Every Newborn Action Plan (ENAP) from other previous action plans remains the key demand-generation role contributed by civil society groups, including engaged parents, families, and communities. Additionally, ENAP has a strong focus on accountability and transparency. All countries are required to make public annual updates to the UN on how they have implemented the evidence-based recommendations noted in their country’s action plan.

One of the major gains of the ENAP was harnessing the entire newborn community of stakeholders and more. Certain groups, not hitherto typically part of the global newborn community of

• BOX 4.2 The Every Newborn Action Plan

Vision

A world where there are no preventable deaths of newborns or stillbirths, where every pregnancy is wanted, every birth celebrated, and women, babies, and children survive, thrive, and reach their full potential.

Every Newborn Action Plan Goals & Targets

1. End preventable newborn death: by 2035, all countries should have a neonatal mortality rate of 10 or less per 1000 live births.
2. End preventable stillbirth: by 2035, all countries should have stillbirth rates of 10 or less per 1000 total births.
3. A global neonatal mortality rate of 7 deaths per 1000 live births by 2035.

Strategic Objectives

Strengthen and invest in care during labor, childbirth, and the first day and week of life

Improve the quality of maternal and newborn care

Reach every woman and every newborn to reduce inequities

Harness the power of parents, families, and communities

Count every newborn: measurement, program tracking, and accountability

Guiding Principles

Country leadership

Integration

Equity

Accountability

Innovation

stakeholders, were actively sought out and engaged as key stakeholders, including mothers' groups, as well as other "communities" such as the maternal, child, and nutrition communities. Furthermore, politicians and high-profile individuals were sought out to act as newborn champions. It is worth emphasizing that in many low- and middle-income countries, more funding is increasingly being generated internally. Thus country-led advocates, policymakers, funders, programmers, and researchers are forming a growing number of key newborn stakeholders. Collaborations have formed around newborn health to develop research infrastructures that function within and across countries and liaise with multinational agencies to evaluate best practices and scale-up. The African Newborn Network, for example, includes Ethiopia, Ghana, Malawi, Mali, Mozambique, South Africa, Tanzania, and Uganda and is funded by the Bill and Melinda Gates Foundation via Save the Children's Saving Newborn Lives Initiative. Another example is the Eunice Kennedy Shriver National Institute of Child Health and Development Global Network for Women and Children's Health. These collaborations include ministries of health, UN agencies, and researchers across many continents and have resulted in networks that have conducted and evaluated community and facility-based interventions to improve maternal and newborn health with the goal of delineating those that may be effective and scalable in low- and middle-income settings (Koso-Thomas et al., 2015). Table 4.2 outlines examples of some of the key stakeholders in global newborn health.

In addition to providing a "north star" for health and development until 2015, the MDGs were successful at leveraging the attention, political will, and resources of the global community, nations, regions, researchers, aspiring innovators, and initiative leaders, all working toward a common goal. The Sustainable Development Goals (SDGs) have been built on the successes and lessons learned from the MDGs and represent a new era of global health and

development. While the SDGs are much more comprehensive, holistic, and ambitious and extend beyond the health and development sectors into a more integrated whole, some critics are challenged by the differences in their design, context, concept, scope, significance, targets, and approach (Fig. 4.7). It remains to be seen how the implementation of these goals will be rolled out, what the financing mechanisms involved will look like, and perhaps, most importantly, how sharp and clear the 17 targets and subtargets will be for policy coherence and how specific, measureable, attainable, relevant, and time-bound (SMART) they are.

The Global Strategy for Women's and Children's Health was launched by the Secretary General of the UN in 2010 when it became increasingly clear that progress toward achieving MDG 4, 5, and 6 was lagging the furthest behind. The overarching goal of the global strategy was to bring together and mobilize a wide array of partners from all sectors to join a global effort to reach the MDGs and improve the health and well-being of women and children in the 49 poorest countries of the world. The Global Strategy has helped to strengthen political commitment, mobilize resources (over US\$40 billion increase in women and children's health between September 2010 and May 2014), focus attention, coordinate, and consolidate efforts, bringing together partners and initiatives such as A Promise Renewed, Family Planning 2020, Every Newborn Action Plan, UN Commission on Life-Saving Commodities, and Ending Preventable Maternal Mortality. Together with working groups on innovations, commodities accountability, and financing, these partnerships are driving maternal, newborn, and child health interventions to scale. The Global Strategy stands on three pillars – partnerships, accountability, and innovation (Temmerman et al., 2015).

Despite increasing global consensus around essential interventions and programs to improve newborn outcome, substantial gaps remain in ensuring that the majority of neonates have access and high uptake (coverage) of these interventions and programs (Fig. 4.8). Lack of resources, including human resources, is a contributor to these gaps, though the complete picture of the causes underlying these inequities is more complicated and remains somewhat controversial. Despite the fact that evidence exists to support the implementation of many low-cost, high-impact interventions for newborns, challenges remain at local and national levels to scale-up sustainability. Differences in context from one low-resource setting to another hinder uniform implementation and scale-up of interventions. The keys to implementation at scale for proven interventions include a deep understanding of the local context, provision of an enabling environment, empowerment of local champions, and engagement of key stakeholders.

There are numerous inequities to combat in the global struggle to improve newborn health. In general, regions that have the highest NMRs also have the lowest healthcare worker density (Lawn et al., 2010). Three-quarters of the world's physicians are working in high-income countries serving approximately one-third of the world's population. Further analysis suggests that in Africa, 3% of the world's healthcare workforce has 1% of the world's expenditure on health to tackle approximately 24% of the global burden of disease (Serour, 2009). In addition to the shortage of the healthcare workforce, most hospitals in sub-Saharan Africa are not equipped to provide even basic neonatal resuscitation (Howie et al., 2008).

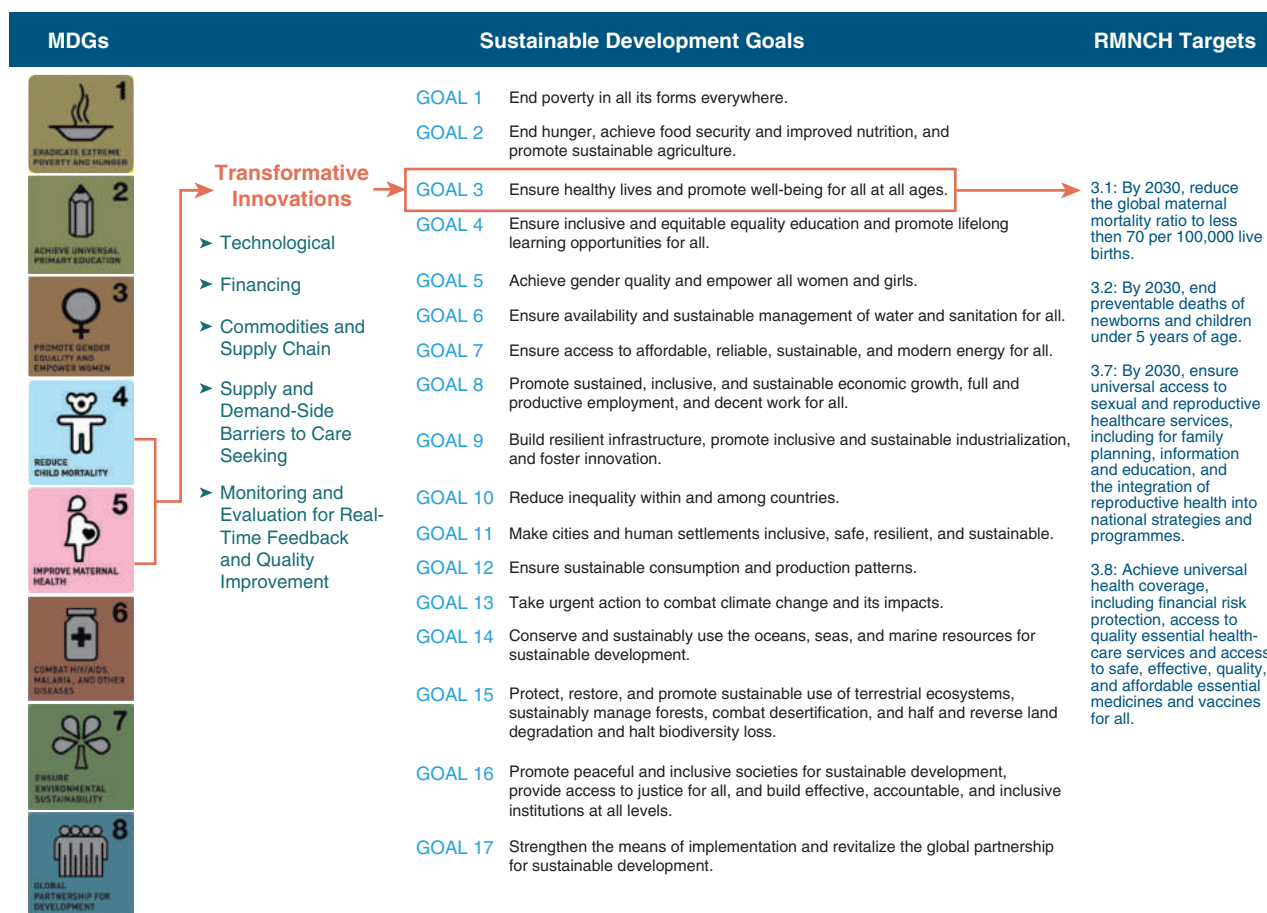

Toward a "Grand Convergence"

A number of authors have modeled analyses that indicate that by making today's medicines, vaccines, and other health tools

TABLE 4.2 Examples of Some of the Key Categories of Stakeholders in Global Newborn Health

| National Governments | Private Foundations | United Nations Agencies | Academic Institutions and Networks | Nongovernmental Organizations | Civil Society Organizations | Other Communities of Practice | Newborn Champions | Bilaterals | Professional Bodies |
|--|---------------------------------------|---|---|--|-----------------------------|-------------------------------|--|---|---|
| Indian Ministry of Health and Family Welfare | Bill and Melinda Gates Foundation | World Health Organization | INDEPTH Network | Save the Children – Saving Newborn Lives | Social Good Moms | Nutrition community | Mrs. Graca Machel – wife of the late President of South Africa, Nelson Mandela | United States Agency for International Development | International Pediatric Association |
| Kenya Ministry of Health | Children's Investment Foundation Fund | United Nations Children's Fund | Healthy Newborn Network | PATH | Kybele, Inc. | Child health community | Secretary Hilary Clinton | United Kingdom Department for International Development | International Federation of Gynecology and Obstetrics |
| Ethiopian Ministry of Health | March of Dimes | United Nations Population Fund | NICHD Global Network for Women and Children's Health | Johns Hopkins Program for International Education in Gynecology and Obstetrics | | Pneumonia community | Prime Minister Erna Solberg of Norway | Norwegian Agency for Development Cooperation | International Confederation of Midwives |

• **Fig. 4.7** Conceptual Framework for How Transformative Innovations in Reproductive, Maternal, Newborn, and Child Health That Were Started in the Millennium Development Goals Era and Continued Through the Sustainability Development Goals Era Might Help Achieve Reproductive Maternal, Newborn Child Health Targets by 2030. *AIDS*, Acquired immunodeficiency syndrome; *HIV*, human immunodeficiency virus; *MDG*, millennium development goal; *RMNCH*, reproductive, maternal, newborn, and child health. (Courtesy of Dr. Cheryl Moyer, University of Michigan, Ann Arbor, MI.)

universally available, and by stepping up tomorrow's innovation efforts, the health gap between high- and low-income countries could be closed within a generation (Jamison et al., 2013). Estimates are that by 2035 such a “grand convergence” in global health is achievable, reducing preventable maternal and child deaths to unprecedented low levels. The authors report that with aggressively scaled-up investments, 10 million lives can be saved annually with huge economic benefits: every dollar invested in low- and middle-income countries would yield US\$9–20. What innovations are necessary to achieve this grand convergence by 2035?

Summary

Global newborn health has gained momentum over the past 15 years. Set against the backdrop of increasing national and governmental awareness coupled with an impressive array of global initiatives, strategies, and action plans, many countries have responded and are beginning to actively invest time and effort toward developing newborn policies, research, and programs. Still, there remains an unfinished agenda. Although the last 25 years represented the period of the greatest health and development improvements in human history, some of the original MDG targets, especially the maternal and child ones, were not achieved. Newborn mortality, especially, is a high global priority.

The conceptual framework utilized by a group of authors is useful to consider. In this model, several innovations are described. These include innovations in technology, commodities, demand-side barriers to care seeking, provision and supply-side issues especially to marginalized populations, financing, better monitoring and measurement, and real-time feedback (Engmann et al., 2016). While we are still in the early days of the SDG era, the previous 15 years and concerted thrust of the global community provide promise that such an accelerated grand convergence can occur.

In addition to ongoing work to improve global newborn survival, the future directions, trends, and themes across newborn health include the following:

1. **Survive and thrive:** incorporating a thrive lens into the current mortality lens is a strategic direction. This may include effective implementation of newborn and developmental milestone screening procedures, promotion of exclusive access and intake of human milk, early referral and treatment when developmental milestones are not attained, and provision of anticipatory guidance and counseling for parents and caregivers.

• **Fig. 4.8** Coverage of Selected Interventions to Improve Neonatal Health in Countdown Countries. IPTp, intermittent preventative treatment in pregnancy; ITN, insecticide-treated bednets. (From Bhutta ZA, Das JK, Bahl R, et al. Can available interventions end preventable deaths in mothers, newborn babies, and stillbirths, and at what cost? *Lancet*. 2014; 384: 347–370.)

2. Quality of care, especially at birth: leveraging the triple return on improved maternal and neonatal mortality and reduced stillbirth.
3. Implementation science: utilizing implementation science to effectively implement newborn programs at scale.
4. Integrating newborn health into the reproductive, maternal, newborn, child, and adolescent health and nutrition spectrum.

5. Newborn health among special populations such as the urban poor, displaced populations, those in emergency settings, and the adolescent.

All who work with mothers and newborns, wherever we are in the world – in high-, middle-, and low-income settings – can play a pivotal role in improving global conditions for the baby. The question is, will we?

Development, Function, and Pathology of the Placenta

EMIN MALTEPE AND ANNA A. PENN

KEY POINTS

- The placenta is the first organ to form in mammals and is required for establishment of a maternal–fetal vascular interface capable of supplying the bioenergetic needs of the developing conceptus.
- Multiple placental cell types engage in highly varied functions, from attachment, invasion, and vascular remodeling to cell fusion, hormone production, and nutrient transport.
- Multiple mechanisms allow transport of waste and nutrients across the placenta, including diffusion, transporter protein-mediated (facilitated diffusion and active transporters), and receptor-mediated mechanisms.
- The placenta is not an inert transport interface. It consumes 40%–60% of the oxygen and glucose delivered to the uterus at term. Thus conditions that alter placental metabolism can indirectly affect nutrient transport to the fetus.
- Maternal and fetal health alter placental function, which in turn influences fetal adaptations and contributes to in utero fetal programming.
- Abnormal placentation and placental infections can lead to preeclampsia (PE), fetal growth retardation, or preterm birth, which can have lifelong bearing on health.
- In the United States, iatrogenic delivery is responsible for almost half the births that occur between 28 and 37 weeks of gestation, primarily caused by placental pathologies such as PE or intrauterine growth restriction.
- Efforts to standardize placental examination after delivery are in progress so that connections between specific placental problems and poor outcomes can be better defined. In parallel, new advanced imaging techniques and biomarkers for placental function are being developed.

The placenta is a remarkable organ. Its brief existence enables the mammalian fetus to survive and thrive within the otherwise inhospitable confines of the intrauterine environment. To accomplish this, the placenta plays a range of roles, from anchoring the conceptus and preventing its rejection by the maternal immune system to enabling the transport of nutrients and wastes between the mother and the embryo/fetus. As with all organs, multiple specialized cell types derived from lineage-committed precursors are responsible for these functions. Genetic, epigenetic, and physiologic cues direct placental development across gestational stages (Maltepe et al., 2010). Impairments in

these processes due to intrinsic or extrinsic insults can lead to placental dysfunction and result in long-lasting increases in disease susceptibility, a process known as fetal programming (Murphy et al., 2006; Eichenwald and Stark, 2008). Both preterm and term infants are at risk from poor placental function, particularly those that are extremely low birth weight (<1 kg). Preterm infants in particular may suffer from placental dysfunction in utero followed by early loss of placental support, including nutrition, hormones, and immune protection. Preterm delivery rates continue to rise while the survival of preterm infants has increased due to numerous advances in medical management and technology (Saigal and Doyle, 2008). This convergence has generated an expanded population of patients admitted to and graduating from intensive care nurseries. Not only are these infants more likely to develop complications such as bronchopulmonary dysplasia, failure to thrive, pulmonary hypertension, cerebral palsy, and blindness, but they are also more likely to develop chronic adult ailments such as diabetes and heart disease. Although further improvements in neonatal care are critical for diminishing the long-term consequences of prematurity, prevention or delay of preterm delivery will have the greatest healthcare impact for this at-risk population. A better understanding of the most common placental pathologies is therefore critically important for advancing maternal, fetal, and adult medicine.

Placental Origin

The mammalian lineage began approximately 200 million years ago with monotremes, or egg-laying mammals, e.g., the echidna and platypus. Echidnas lay their eggs into an egg pouch, whereas platypuses lay their eggs into a burrow, where the mother curls around them to provide them with warmth and protection. Lacking a true placenta, these embryos rely on a yolk sac to provide them with nourishment. The duck-billed platypus, on the other hand, develops a primitive allantoic vitelline placenta from trophoblast (TE)-like cells called vitellocytes. These support the embryo to the 19-somite stage, indicating that the molecular mechanisms enabling segregation of extraembryonic TE from embryonic tissues may have predated evolution of a true placenta (Hughes and Hall, 1998; Selwood and Johnson, 2006). Marsupial embryos also have yolk sacs but are born live. Although the primitive TE cells

surrounding the early marsupial embryo produce a single cell-layered transport interface that may represent a primitive placenta, it can only provide for the metabolic demands of embryonic/fetal development for a short while, accounting for the short internal gestation period of marsupials (Renfree, 2010).

Eutherian, or true placental, mammals diverged from marsupials approximately 140 million years ago. The placenta is a tremendously successful evolutionary adaptation that has enabled the creation of around 18 taxonomic orders grouped into four superorders. These groups gave rise to many lineages, each of which evolved independently in different geographic locations and in response to differing environmental challenges. There is thus a vast variety of placental forms, and identifying what the original placenta looked like is therefore quite difficult, but it may have been hemochorial, discoid, and labyrinthine (Wildman et al., 2006), similar to that observed in rodents. The placenta is likely the most mutable of all organs, with at least 20 identifiable types, depending on the manner of classification (Benirschke and Kaufmann, 1995). Perhaps not surprisingly, divergence among placental types may have developed a large number of species-specific pathologies, leading to potential limitations in cross-species investigations (Gutmacher et al., 2014).

Internal development supported by a placenta provides many benefits including protection from environmental fluctuations in temperature, oxygen, and osmolarity, as well as protection from predation (Shine, 1989; Clutton-Brock, 1991; Wourms and Lombardi, 1992). It also allows females to produce larger offspring with a higher rate of survival due to enhanced feeding, digestion, movement, or behavior (Amoroso, 1968; Baylis, 1981; Wourms, 1994). However, this also comes with high energetic costs to the mother (Boehlert et al., 1991; Qualls and Shine, 1995). In addition to limiting maternal mobility, increasing time between births, and decreasing frequency of reproduction (Thibault and Schultz, 1978; Goodwin et al., 2002), internal, placenta-supported reproduction demands adaptation of multiple maternal organ systems during pregnancy. The complexity of this benefit–risk ratio may also add to the many placental variations that exist.

Development of the Placenta

Trophoblast Lineage Allocation

The placenta is the first organ to form in mammals. This is because it is required for establishment of a functional maternal–fetal vascular interface capable of supplying the bioenergetic needs of the developing conceptus (Maltepe et al., 2010). The fertilized embryo undergoes a series of cell divisions before implantation, to produce up to eight seemingly identical cells called blastomeres. Three further sets of divisions generate the blastocyst, consisting of two distinct cell populations. Surrounding the blastocyst is the TE, which gives rise to the placenta. The inner cell mass (ICM), located inside the blastocyst, gives rise to the embryo and visceral endoderm (Nishioka et al., 2009; Sasaki, 2010). In mice, each blastomere is able to generate either ICM or TE derivatives and is thus totipotent. This also occurs in humans (Zdravkovic et al., 2015). Once TE or ICM commitment occurs, however, it is considered largely irreversible. Importantly, however, individual blastomeres are found to harbor intrinsic biases regarding which lineage they adopt as early as the four-cell stage (Piotrowska-Nitsche et al., 2005; Tabansky et al., 2013) and which appear to depend on positional cues (Nishioka et al., 2009).

Multiple factors govern lineage allocation. One major determinant includes differences in polarity and adhesion between inner and outer cells of the blastocyst that are associated with differential

activation of the Hippo signaling cascade (Nishioka et al., 2009; Hirate et al., 2013). Hippo helps restrict expression of key lineage regulatory genes such as *Cdx2* that are stochastically expressed as early as the eight-cell stage in mice but restricted thereafter to the TE (Dietrich and Hiiragi, 2008). The Hippo pathway is inactivated in outer TE cells, resulting in nuclear localization of the transcriptional coactivator Yes associated protein (YAP), which interacts with TEA domain transcription factor 4 (TEAD4) to drive Caudal type homeobox 2 (*Cdx2*) gene expression (Nishioka et al., 2008). Notch signaling also acts in parallel with Hippo to promote *Cdx2* expression in this process (Rayon et al., 2014). Positional cues governed by E-cadherin expression help regulate Hippo signaling. Cell–cell contact within inside cells of the ICM activates Hippo and suppresses nuclear YAP activity. Signaling cascades implicated in this include the LATS2 kinase. For example, Hippo can be suppressed by a dominant negative form of the LATS2 kinase or by combined LATS1/2 deficiency. This results in ICM cells exhibiting nuclear YAP localization, *Cdx2* expression, and TE fates (Nishioka et al., 2009), placing LATS1/2 downstream of E-cadherin-dependent signaling. In mice, CDX2 helps repress genes critical for ICM identity, such as *Oct4* and *Nanog*. Its absence in mouse embryos results in the lack of TE differentiation, and all cells of the blastocyst stage embryo express the typically ICM-restricted OCT4 protein (Niwa et al., 2005). This ability is species dependent, however, and is not observed in bovine (Berg et al., 2011) or human blastocysts (Niakan and Eggan, 2013). Amazingly, in mice its expression is sufficient to convert embryonic stem cells (ESCs) into trophoblast stem cells (TSCs) that can contribute to all lineages found within the placenta (Tanaka et al., 1998; Niwa et al., 2005). *Cdx2* expression is further maintained in mice via a positive feedback loop driven by the combinatorial activities of the transcription factors Eomesodermin (EOMES), ETS-related transcription factor 5 (ELF5), ETS proto-oncogene 2 (ETS2), and transcription factor AP-2, gamma (TCFAP2c) that help maintain the TE lineage (Yamamoto et al., 1998; Russ et al., 2000; Auman et al., 2002; Werling and Schorle, 2002; Donnison et al., 2005; Georgiades and Rossant, 2006; Ng et al., 2008; Weber et al., 2010). Interestingly, ELF5, CDX2, and EOMES can collaborate to regulate hundreds of TSC genes by binding to enhancer elements that harbor endogenous retrovirus-derived sequences, indicating that these serve as trophoblast-specific enhancer elements in mice (Chuong et al., 2013). This opens the exciting possibility that differences in the incorporation of these foreign viral elements across different placental mammals may have contributed to the diversity of placental structures seen across the animal kingdom.

Uterine evolution paralleled placental evolution in eutherian mammals. This was recently found to involve large-scale and rapid changes in endometrial gene regulatory networks mediated by ancient transposable elements. These modulate responses to pregnancy hormones as well as other pathways to ensure pregnancy success (Lynch et al., 2011; Lynch et al., 2015). Thus a set of genetic tricks coupled with host–virus interactions enabled the rapid evolution of the placenta–uterus axis in mammals and helped contribute to the diversity of mammalian life forms and modes of procreation observed today.

Trophoblast Differentiation

The placenta is comprised of multiple different cell types that engage in highly varied functions, ranging from attachment, invasion, and vascular remodeling to cell fusion, hormone production, and nutrient transport (Maltepe et al., 2010). Thus trophoblast-specific

• **Fig. 5.1** Embryonic Development in the Mouse Conceptus. At the blastocyst stage, the conceptus is comprised of an inner cell mass (ICM) that gives rise to the embryo proper (epiblast), overlaid by a layer of primitive endoderm (hypoblast) that gives rise to the visceral and parietal endoderm. The outer cells comprise the trophoctoderm (TE) that gives rise to the placenta. TE cells near the ICM are referred to as polar TE, while TE cells not in contact with the ICM are referred to as mural TE. The mural TE gives rise directly to parietal trophoblast giant cells in the initial wave of trophoblast differentiation. These cells aid the initial attachment and invasion process. The polar TE differentiates into the ectoplacental cone and extraembryonic ectoderm. The ectoplacental cone resides closest to the implantation site and also gives rise to lineages that further help incorporate the conceptus into the receptive uterus. The extraembryonic ectoderm resides closest to the developing epiblast and gives rise to lineages comprising the placental transport interface, such as the syncytiotrophoblast. TGCs, Trophoblast giant cells.

progenitors need to enact a complex set of lineage restriction decisions to help form a functioning placenta.

The isolation of rodent TSCs, the extraembryonic equivalent of ESCs, has dramatically increased our understanding of cell fate decisions in the placenta (Tanaka et al., 1998). Combined with genetic approaches in mice and analyses of resultant placental phenotypes in vivo, derivation of “knock-out” TSC lines has enabled dissection of lineage commitment decisions within the placenta with great precision. For the human placenta, in vitro experiments with primary cytotrophoblasts (CTBs) as well as ex vivo culture of placental explants have yielded a great deal of information regarding placental development. Human ESCs can also be induced to differentiate into the trophoblast lineage by activating bone morphogenetic protein 4 (BMP4)-dependent signaling pathways (Li and Parast, 2014). Additionally, the recent derivation of single blastomere-derived cell lines from human embryos that can differentiate along the trophoblast lineage is aiding our understanding of human placental development (Zdravkovic et al., 2015). These have been combined with pathologic analyses of placentas following delivery or pregnancy terminations. While primary human trophoblast progenitor cell lines have recently been derived (Genbacev et al., 2011), the exact equivalents of TSCs have not yet been isolated in humans.

TSCs can be derived from mouse blastocysts on fibroblast feeder cells with the addition of fibroblast growth factor 4 (FGF4). Feeder cells produce growth factors such as the TGF- β family member Nodal (Erlebacher et al., 2004; Guzman-Ayala et al., 2004), along

with extracellular matrix-dependent cues (Choi et al., 2013) that maintain TSC proliferation and help prevent their differentiation. In utero, this environment is only maintained for approximately 3 days following implantation, as TSCs cannot be derived from mouse embryos past embryonic day 6.5 (Uy et al., 2002). Removal of growth factor, feeders, or feeder-conditioned medium triggers loss of TSC proliferation as well as markers associated with “stemness” (Roberts and Fisher, 2011). Depending on environmental or culture conditions, these cells then differentiate into the various cells that comprise the placenta. In the mouse, the extraembryonic ectoderm differentiates into cells that comprise the chorion and labyrinth, which perform the transport functions of the placenta, whereas the ectoplacental cone, located nearer to the uterine implantation site, differentiates into the spongiotrophoblast layer as well as glycogen trophoblasts and trophoblast giant cells (TGCs) (Fig. 5.1).

To function as a transport organ, the placenta must establish an extensive vascular interface between the maternal and fetal circulatory systems. Humans and rodents have a hemochorial placenta, which means that the maternal vascular space comes in direct contact with differentiated trophoblasts, not endothelial cells (Benirschke and Kaufmann, 1995). In humans, trophoblasts lining maternal arteriolar spaces are relatively well characterized (Red-Horse et al., 2004), but very little is known about the cells associated with the draining vascular bed, for example. In mice, there appear to be at least five distinct populations of TGCs that lie at various positions within these maternal vascular spaces and are defined by their

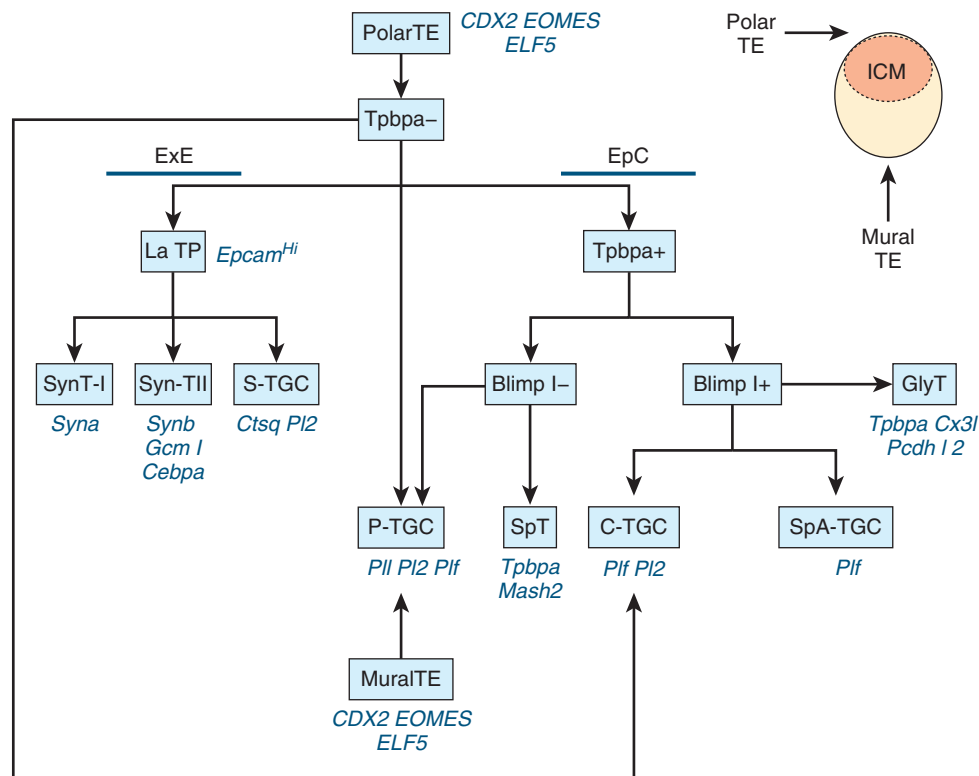

location and lineage-specific gene expression (Simmons et al., 2007). These arise from various sources (see Fig. 5.1). Their “giant” size is, in part, a reflection of their DNA content, which continuously replicates without engaging in cell division via a process called endoreplication (Edgar et al., 2014). Endocycles are thought to be used by cell types that need to be very large or that are highly metabolically active. Consistent with this, TGCs in the mouse placenta are responsible for the bulk of placental hormone production (Soares et al., 2007). In humans, placental hormones are produced by the syncytiotrophoblast (SynT) layer, potentially accounting for the reduced ploidy of invasive trophoblast subtypes in this species compared with rodents, although they still appear to exhibit a significant amount of aneuploidy (Weier et al., 2005).

Trophoblast Invasion

Primary TGCs differentiate from the mural TE, and this represents the first terminally differentiated cell type in mice to aid in implantation. In humans, the initial wave of invasion following implantation is thought to occur via formation of a primitive syncytium, through

which invasive CTBs push following approximately day 13 or 14 of gestation (Cantor and Ginsberg, 2012). This early wave of syncytialization does not occur in rodents. In mice, the remaining secondary TGCs differentiate either from trophoblast specific protein alpha (Tpbpa)/4311+ outer ectoplacental cone cells or from Tpbpa/4311– chorionic progenitors (Simmons et al., 2007) (Fig. 5.2). Secondary TGCs come in various forms that have differing locations as well as characteristics. As the name implies, spiral artery (SpA) TGCs invade the spiral arteries and displace the smooth muscle and endothelial cells to remodel them, canal TGCs line the large vascular spaces delivering maternal blood to the base of the labyrinth, sinusoidal TGCs sit within the small vascular spaces of the labyrinth, and parietal TGCs surround large pools of deoxygenated blood that ultimately drain into the maternal uterine veins.

In addition to their location, these cells can be identified based on lineage-specific gene expression (see Fig. 5.2), although very few unique identifiers are known at this time, and all can be derived in vitro following TSC differentiation (Simmons et al., 2007). A growing list of transcription factors and signaling molecules are

• **Fig. 5.2** Trophoblast Lineage Determination in the Mouse Placenta. Cell type-specific genes are indicated in blue. Mural trophoblast (TE) cells give rise directly to parietal trophoblast giant cells (TGCs). Parietal TE cells, from which trophoblast stem cells (TSCs) are derived, are defined by their expression of key transcription factors including CDX2, EOMES, and ELF5 and can be maintained in vitro by exogenous fibroblast growth factor 4 as well as Nodal signaling. These give rise to all cell types within the mature placenta. Polar TE cells can also give rise directly to parietal TGCs via passage through a trophoblast specific protein alpha (Tpbpa)/4311 negative (–) state. Alternatively, Tpbpa– progenitors can give rise to labyrinth trophoblast progenitors (La TP) characterized by high EpcAM expression that gives rise to lineages that populate the exchange interface. These are the two syncytiotrophoblast (SynT) lineages—SynT-I and SynT-II, as well as the sinusoidal TGCs (S-TGC). Tpbpa+ progenitors, on the other hand, further differentiate through either a Blimp1+ or – state into spongiotrophoblasts (SpT), glycogen trophoblasts (GlyT), or multiple additional types of TGCs, including spiral artery-associated TGCs (SpA-TGCs) and canal TGCs (C-TGCs). Each terminally differentiated cell type is associated with a unique combination of lineage-specific genes that enable their identification in vitro and in vivo (indicated in blue). Epc, Ecto-placental cone; ExE, extraembryonic ectoderm; ICM, inner cell mass; P-TGC, parietal TGC.

known to be critical for these differentiation events and have been reviewed extensively (Hu and Cross, 2010; Maltepe et al., 2010; Pfeffer and Pearton, 2012; Soares et al., 2012; Knofler and Pollheimer, 2013; Knott and Paul, 2014; Latos and Hemberger, 2014; Soncin et al., 2015). An organizational chart depicting the cell fate regulatory hierarchy within the placenta can be made based on our current understanding but still remains poorly characterized when compared with other systems such as hematopoiesis. CDX2-, EOMES-, and ELF5-positive TSCs sit at the apex of this hierarchy (see Fig. 5.2).

Trophoblasts that invade and line blood vessels appear to do so via two different mechanisms: (1) vascular invasion with endothelial mimicry and (2) vasculogenic mimicry (Rai and Cross, 2014). In the former, trophoblasts invade into and displace maternal endothelial cells from within maternal arterioles and include SpA-TGCs in mice or endovascular trophoblasts (EVTs, also known as extravillous trophoblasts) in humans. During vasculogenic mimicry, however, trophoblasts undergo morphogenesis to create vascular tubes de novo. Sinusoidal TGCs perform this function in mice. Whether this also occurs in human placentation is not clear. Transplanting trophoblasts subcutaneously in mice or culturing them as 3-dimensional trophospheres in vitro allows one to visualize them from de novo vascular spaces, where they generate tumors harboring large blood sinuses surrounded by trophoblasts, as opposed to host endothelium (Kibschull and Winterhager, 2006; Rai and Cross, 2014). Many pathways known to regulate endothelial development also drive trophoblast differentiation and formation of the maternal–fetal vascular interface (reviewed in Rai and Cross, 2014). For example, TGCs produce both vascular endothelial growth factor (VEGF) and placenta growth factor (PlGF) and express VEGF receptors -1 and -2, suggesting both autocrine and paracrine roles (Achen et al., 1997; Abbott and Buckalew, 2000; Hirashima et al., 2003). Additionally, Notch signaling, known to be critically important for vascular endothelium, is also important for differentiation of SpA-TGCs and Canal (C)-TGCs in the mouse placenta (Hunkapiller et al., 2011; Gasperowicz et al., 2013). These same factors are also expressed in homologous cells within the human placenta (Zhou et al., 2003a, 2003b; Hunkapiller et al., 2011). Furthermore, the endothelium and trophoblast are primary regulators of hemostasis in the adult and fetal circulation. Trophoblasts can regulate the coagulation cascade like endothelial cells and produce such molecules as thrombomodulin, tissue factor, tissue factor pathway inhibitor, annexin V, and endothelial protein C receptor (Wang et al., 1999; Lanir et al., 2003; Sood et al., 2006). These factors are critical for preventing thrombotic or hemorrhagic events from occurring in the developing placenta. Consistent with this, tissue factor deficiency in mice results in early embryonic lethality associated with massive hemorrhage at this extremely vascular interface (Erlich et al., 1999). Thus mammalian placentas have solved the problem of hemochorial placentation by having trophoblasts take over functions typically performed by endothelial cells.

Remodeling of uterine vasculature is critical for successful pregnancy in humans and mice (Pijnenborg et al., 2006; Maltepe et al., 2010; Soares et al., 2012; Rai and Cross, 2014). The equivalents of TGCs in humans, invasive EVT, are derived from column CTB progenitors located at the tips of anchoring villi (Fig. 5.3). They migrate through the uterine parenchyma via interstitial invasion, in search of maternal spiral arterioles and veins. This invasion peaks early in pregnancy, around 9 to 12 weeks of gestation (Pijnenborg et al., 1981). EVTs then breach the spiral arterioles, via a process termed endovascular invasion, and replace

• **Fig. 5.3** Human Placenta at Mid Gestation. The human (and mouse) placenta is disc shaped (discoid) and hemochorial; i.e., fetal trophoblasts are in direct contact with maternal blood. In contrast to the labyrinthine placenta in mice, the human placenta is comprised of chorionic villi that project into the intervillous space bathed by maternal blood. Fetal blood vessels coursing through the umbilical cord branch when they reach the placenta and dive into the chorionic villi where gas, nutrient, and waste exchange occurs. Tips of anchoring villi attach to the uterine wall (basal plate) and send out waves of invasive cytotrophoblasts (also known as extravillous trophoblasts) to both anchor the placenta and establish blood flow to it. (Adapted from Hunkapiller NM and Fisher SJ. *Methods Enzymol.* 2008;445:281–302.)

resident endothelial and smooth muscle cells (Red-Horse et al., 2006). This results in these high resistance vessels being remodeled into low resistance/high capacitance conduits necessary for proper fetal perfusion as well as modulation of maternal hemodynamics (Red-Horse et al., 2004). While EVT interactions with veins are largely confined to the inner surface of the uterus, they migrate along much of the intrauterine course of maternal arterioles. Although endovascular invasion begins quite early, and typically begins within the center of the placental bed, uterine arterial blood only begins to flow into the intervillous space by the end of the first trimester. Before this point, EVTs paradoxically plug these vessels, preventing blood flow to the placenta. As a result, all of first trimester placental development occurs in a highly hypoxic environment with the bulk of placental nutrients being provided by endometrial secretions (i.e., histiotrophic nutrition) (Burton, 2009). Only about one-third of the uterine SpAs are actually invaded by 18 weeks' gestational age (Pijnenborg et al., 1983), indicating that the more lateral arteries are only invaded throughout the second and third trimesters in a progressive manner (Brosens et al., 2011; Pijnenborg et al., 2011), because most are completely remodeled when examined following delivery at term.

Following unplugging of these vessels, maternal blood begins to bathe floating chorionic villi that are covered by a layer of multinucleated SynTs. SynTs form as a result of the fusion of lineage-committed progenitors. The need for multinucleated syncytium formation is not clear but may have been driven

evolutionarily by a response to viral infections that may help minimize pathogen transmission to the fetus (Tsurudome and Ito, 2000). A combination of fusogenic protein expression, particularly syncytins (Blond et al., 2000; Mi et al., 2000; Malassine et al., 2007; Chen et al., 2008; Esnault et al., 2008; Simmons et al., 2008; Dupressoir et al., 2009; Dupressoir et al., 2011), and dramatic cytoskeletal rearrangement appears to be essential for this trophoblast fusion. Cytoskeletal rearrangement is a common theme in trophoblast differentiation in general (Parast et al., 2001). For example, calponin 3-mediated actin rearrangement can promote SynT fusion (Shibukawa et al., 2010), while caspases can remodel the fodrin cytoskeleton during this process (Gauster et al., 2010), and stathmin expression, a microtubule regulatory protein, is associated with invasive trophoblast migration (Yoshie et al., 2008). Along these lines, invasive TGCs in mice and EVT_s in humans exhibit robust microtubule and actin cytoskeletons, whereas the cytoskeletal network in multinucleated SynT_s found in both species is severely disrupted (Choi et al., 2003; Zhou et al., 2014). Consistent with this, microtubule or actin disrupting agents direct block TGC formation and direct TSC differentiation along the SynT lineage (Choi et al., 2013). Additionally, caspase 8 activity, frequently implicated in apoptosis, aids this process during human SynT formation (Huppertz et al., 1999). These cytoskeletal changes are frequently accompanied by another apoptosis-associated process—externalization of phosphatidylserine to the outer leaflet of the plasma membrane. Typically acting as an “eat me” signal for the clearance of apoptotic cells, phosphatidylserine externalization is associated with SynT fusion (Lyden et al., 1993; Huppertz and Gauster, 2011). Apoptosis is not completed during SynT formation, however, and the syncytium is maintained in this “preapoptotic” state until being sloughed off into the maternal circulation. Other molecules such as connexins are also known to be critical for SynT formation (Kibschull et al., 2008). CD98, an amino acid transporter, also plays a role (Kudo et al., 2003; Kudo and Boyd, 2004; Dalton et al., 2007), and its actions can be opposed by placental protein 13, a galectin family member (Than et al., 2004). In addition to regulating amino acid transport, CD98 can also interact with cell surface integrins to regulate cell morphology and invasion (Cantor and Ginsberg, 2012), playing a unique dual role in the nutrient transport and fusion capabilities of SynT_s. As a result of the dramatic cytoskeletal changes required for cell fusion, in addition to changes in the composition of the membrane lipid bilayer, the biophysical properties of the SynT_s change to become much more rigid, possibly aiding the infection barrier properties of the placenta (Zeldovich et al., 2013).

Analysis of human EVT invasion *in situ* and *in vitro* established that a unique epithelial-to-endothelial switch is a vital component of this process (reviewed in Red-Horse et al., 2004). Initially, CTB progenitors in floating villi express E-cadherin (epithelial cadherin) and integrin $\alpha 6 \beta 4$. Upon differentiation, these cells repress these molecules and upregulate other adhesion molecules such as vascular endothelial cadherin, $\alpha 5 \beta 1$, $\alpha V \beta 3$, PECAM-1, and VCAM-1 as well as the matrix metalloproteinase MMP-9. Other data suggest that CTB differentiation/invasion also entails a switch from a venous to an arterial phenotype in terms of the cells' expression of Eph and ephrin molecules (Red-Horse et al., 2005) and the modulation of Notch family members (Hunkapiller et al., 2011). This change is accompanied by an induction of several growth factors and receptors (e.g., VEGF and angiopoietin family members) that function during conventional vasculogenesis and angiogenesis, as well as placental development in other species (Andraweera et al., 2012; Chen and Zheng, 2014).

Placental Functions

Transport

The transport functions of the placenta are performed by the multinucleated SynT_s that sit at the maternal–fetal interface. Multiple mechanisms allow transport of waste and nutrients across the placenta (Dilworth and Sibley, 2013). The simplest is diffusion. The high surface area of the placental transport interface, along with the hemochorial nature of the rodent and human placentas, enables efficient diffusion across the placenta. The rate of diffusion depends on the molecular properties and concentrations of the solute, however, in addition to the composition of the exchange barrier (Sibley and Boyd, 1988). In the human placenta at term, a single SynT layer separates maternal blood from fetal capillary endothelium, whereas in the mouse, two SynT layers as well as an sinusoidal (S)-TGC layer, surprisingly, separate the vascular spaces (Rossant and Cross, 2001). These layers are progressively thinned out to minimize their barrier properties and increase the surface area for exchange (Simmons et al., 2008). Oxygen is transported across the placenta via passive diffusion, aided by the high affinity of fetal hemoglobin and the concentration differential across the maternal–fetal vascular beds. The orientation of the maternal and fetal vascular blood spaces produces a countercurrent exchange mechanism in mice. This maximizes transport efficiency in rodents, whereas the human placenta has a less efficient multivillous arrangement, which necessitate a larger placental size relative to the mouse (Benirschke and Kaufmann, 1995).

Hydrophilic molecules do not readily cross plasma membranes. Transporter protein-mediated mechanisms are typically required for transporting hydrophilic molecules. Classic transporter proteins include facilitated diffusion transporters, i.e., the glucose transporter (GLUT) family (Jansson et al., 1993) as well as active transporters, i.e., transporters associated with calcium transport (Belkacemi et al., 2005) and the amino acid transporters (Desforages and Sibley, 2010). Transport can occur down a concentration gradient, as is the case with GLUT1-mediated glucose transport (Desforages and Sibley, 2010), or against a concentration gradient, as is the case with calcium (Dilworth et al., 2010) and amino acid transport (Battaglia, 2007). Interestingly, nearly all amino acids in the fetal circulation are found at higher levels than in the maternal circulation, indicating active uptake and/or synthesis of these nutrients via the placenta or fetus.

The fetal–placental unit is both physically and metabolically interconnected with each other and the maternal circulation. Ultimately, all fetal–placental metabolism is constrained by the nutrients delivered from the maternal circulation. However, the placenta and fetal liver are both capable of producing and metabolizing various nutrients that impact their levels in the fetal–placental circulation largely independent of placental transport mechanisms (Cetin, 2001). This has been well described in ovine species, wherein the fetal liver of sheep *in utero* actively produces large quantities of serine and glutamate that are consumed by its placenta (Cetin et al., 1992; Chung et al., 1998). In the placenta, serine is converted to glycine via a process that contributes to one-carbon metabolism-dependent DNA methylation pathways that play important roles in cell fate regulation and growth mechanisms (Amelio et al., 2014). Additionally, nonglucose carbohydrates such as fructose, mannose, inositol, and sorbitol are also either transported by or synthesized in the placenta (Jauniaux et al., 2005; Battaglia, 2007) and play important roles in regulating fetal growth as well as in redox regulation.

Finally, antibody-mediated immunity is transferred from mother to fetus across the placenta via receptor-mediated mechanisms (Saji et al., 1999; Schneider and Miller, 2010). Immunoglobulin G (IgG) transport across the human placenta, for example, begins at approximately 16 weeks' gestation, and fetal serum IgG levels reach maternal levels by 26 weeks' gestational age. This process is highly efficient, enabling fetal concentrations to exceed maternal values at term.

Metabolism

The placenta is not an inert transport interface. It consumes 40%–60% of the oxygen and glucose delivered to the uterus at term, despite only comprising approximately 10%–20% of the total mass of the uterus at that time (Bell et al., 1986; Carter, 2000). Changes in this metabolism can regulate placental biology. Mitochondrial fusion, a process that enables greater mitochondrial bioenergetic capacity, is critical for invasive TGC formation in mice, triggering placental failure when compromised (Chen et al., 2003; Alavi et al., 2007). Interestingly, mitochondrial fusion can promote cardiomyocyte differentiation as well, highlighting conserved mechanisms between cellular metabolism and cell fate determination (Kasahara et al., 2013). Thus alterations of placental metabolic function can impact oxygen and nutrient delivery to the fetus, both by altering placental metabolic demand intrinsically, as well as by impacting cell fate regulatory pathways. Primary culture of human CTBs indicates that they exhibit high rates of aerobic glycolysis when compared with other terminally differentiated adult cells (Bax and Bloxam, 1997), much like rapidly proliferating cancer cells that rely on high glycolytic flux rates to augment biosynthetic precursor production. Aerobic lactate production, i.e., the Warburg effect, also allows the placenta to produce and transfer large amounts of lactate to the fetus, which can readily oxidize it. Interestingly, the placenta also appears able to metabolize lactate during mid gestation but loses this ability by term (Carter et al., 1993). These studies additionally suggest that glycogen breakdown (glycogenolysis) helps supply the high rates of glucose consumption in proliferating trophoblasts before differentiation into terminally differentiated SynTs. Interestingly, excess glycogen accumulation has been noted within the SynT layer of some human preeclampsia (PE) placentas (Arkwright et al., 1993), consistent with their altered turnover and suggesting a potential link to altered glucose metabolism in the setting of this pregnancy complication. Importantly, epidemiologic studies confirm that derangements in glucose and fatty acid metabolism may drive pregnancy complications. For example, maternal gestational diabetes mellitus (GDM) and obesity are independently, and additively, associated with elevated rates of PE (Catalano et al., 2012) as well as spontaneous preterm birth (Shaw et al., 2014). There may be shared mechanisms involving impaired trophoblast invasion contributing to PE and preterm labor (PTL) pathogenesis. For example, up to 30% of patients with spontaneous PTL have placental lesions consistent with impaired SpA remodeling typically observed during PE (Kim et al., 2002; Kim et al., 2003; Romero et al., 2014). Thus improving our understanding of the links between placental metabolism and placental development may shed light on the growing epidemic of preterm birth.

Metabolic stressors such as hypoxia at high altitude, or placental underperfusion associated with intrauterine growth restriction (IUGR), alter placental metabolism in particular ways. During isolated hypoxia induced at high altitude, for example, the human placenta appears to decrease its consumption of oxygen in favor

of glycolysis to maintain its bioenergetic needs (Postigo et al., 2009), which preserves placental growth. While preserving fetal oxygen (O_2) delivery, this comes at the expense of glucose, however (Illsley et al., 2010). Given that fetal hypoglycemia is strongly associated with fetal growth restriction, this limits fetal growth. With maternal undernutrition, however, where uterine O_2 delivery is relatively spared, glucose delivery to the fetus is compromised (Coan et al., 2010; Sandovici et al., 2012) in a manner associated with restricted placental growth. Given that the placenta is a complex organ with multiple different cell types (Simmons et al., 2007, 2008), it is likely that changes in placental cellular composition due to alterations in cell fate regulatory pathways play important roles in the reallocation of placental metabolic flux patterns. Consistent with this, maternal calorie restriction leads to a loss of glycogen trophoblasts in the mouse (Coan et al., 2010). Importantly, isolated hypoxia results in increased Hypoxia-inducible Factor-1 (HIF-1) levels and target gene expression in the human placenta (Nevo et al., 2006; Ietta et al., 2007; Zamudio et al., 2007), and HIF activity regulates trophoblast cell fate decisions, suggesting a potential contribution to these pathologic changes (Cowden Dahl et al., 2005; Maltepe et al., 2005; Choi et al., 2013; Zhou et al., 2014). HIF activity can mediate metabolic adaptation to hypoxia via numerous ways (Semenza, 2010), including repressing mitochondrial O_2 consumption while increasing glycolysis and modulating glucose transport as well as amino acid metabolism.

Endocrine Function

In addition to performing the essential transport functions of the placenta in humans, SynTs secrete numerous pregnancy-related hormones (Maltepe et al., 2010). Mammalian placenta produces a greater diversity of hormones in greater quantity than any other single endocrine tissue. Near term, steroid hormones (primarily estrogens and progestins) are being made at the rate of 0.5 grams per day, and protein hormones (lactogens, growth factors, and other hormones similar to those of the hypothalamic–pituitary–adrenal [HPA] axis) are being made at more than twice this rate. Many of these hormones are species specific, but the categories of hormones (i.e., steroids, pituitary-like, hypothalamic-like etc.) and their endocrine, paracrine, and autocrine functions in pregnancy are frequently conserved (Table 5.1).

Steroid Hormones

The placenta is an “incomplete” steroidogenic organ and does not express a complete set of enzymes for de novo production of estrogens and progestins. Steroid hormone synthesis in the placenta is dependent on precursors from mother and fetus, leading to the concept of an integrated *maternal–fetal–placental unit* (Ryan, 1980). Fig. 5.4 diagrams the tissues and enzymes that participate in the biosynthesis of progestins and estrogens (Kallen, 2004). The concentration of steroid hormones in the maternal circulation increases dramatically throughout gestation (Tulchinsky et al., 1972).

Progesterone

Maternal cholesterol, derived from low-density lipoprotein, is transported to the placenta and bound to low-density lipoprotein receptors on SynTs, where it is incorporated by endocytosis and hydrolyzed to free cholesterol in lysosomes (Hussa, 1980). There is no significant 3-hydroxy-3-methylglutaryl coenzyme A activity in human placenta and thus maternal cholesterol must be used

TABLE 5.1 Placental Classification (Incorporating the 2014 Amsterdam Placental Workshop Group Criteria)

1. Placental Vascular Processes
 - a. Maternal stromal-vascular lesions
 - Developmental
 - Superficial implantation/decidual arteriopathy
 - Increased immature extravillous trophoblast
 - Malperfusion
 - Global/partial
 - Early: distal villous hypoplasia
 - Late: accelerated villous maturation
 - Segmental/complete
 - Villous infarct(s)
 - Loss of integrity
 - Abruptio placenta (atrial)
 - Marginal abruption (venous)
 - Acute
 - Chronic
 - b. Fetal stromal-vascular lesion
 - Developmental
 - Villous capillary lesions
 - Delayed villous maturation (maturation defect)
 - Dysmorphic villi
 - Malperfusion
 - Global/partial
 - Obstructive lesions of umbilical cord
 - Recent intramural fibrin in large fetoplacental vessels
 - Small foci of avascular or karyorhectic villi
 - Segmental/complete
 - Chorionic plate or stem villous thrombi
 - Large foci of avascular or karyorhectic villi
 - Loss of integrity
 - Large vessel rupture (fetal hemorrhage)
 - Small vessel rupture (fetomaternal hemorrhage)
 - Villous edema
2. Placental Inflammatory Immune Processes
 - a. Infectious inflammatory lesions
 - Acute
 - Maternal inflammatory response: chorioamnionitis, subchorionitis
 - Fetal inflammatory response: chorionic/umbilical vasculitis
 - Chronic
 - Villitis (CMV, others)
 - Intervillositis (malaria, others)
 - b. Immune/idiopathic inflammatory lesions
 - Villitis of unknown etiology and related/associated lesions
 - Chronic villitis
 - Chronic chorioamnionitis
 - Lymphoplasmacytic deciduitis
 - Eosinophil T-cell fetal vasculitis
 - Chronic histiocytic intervillositis
3. Other Placental Processes
 - Massive perivillous fibrin(oid) deposition (maternal floor infarction)
 - Abnormal placental shape or umbilical insertion site
 - Morbidly adherent placentas (accreta)
 - Meconium-associated changes
 - Increased circulating nucleated red blood cells

CMV, Cytomegalovirus.

From Redline, R.W. Classification of placental lesions. *Am J Obstet Gynecol*. 2015 Oct;213(4 Suppl):S21-8.

for production of pregnenolone, the first step in steroid synthesis. Cholesterol is converted to pregnenolone in the mitochondria by cytochrome P450 cholesterol side-chain cleavage enzyme. After transfer to the cytosol, progesterone is produced from pregnenolone by type-1 3β -hydroxysteroid dehydrogenase (Osathanondh and Tulchinsky, 1980; O'Connor et al., 1998). Before the ovarian-placental shift, the corpus luteum of pregnancy is the primary source of progesterone, but by 35 to 47 days postovulation the placenta produces enough progesterone to maintain pregnancy (Csapo et al., 1973). The majority (>90%) of progesterone goes to the mother and the rest to the fetus. A limited amount of pregnenolone is also released into the circulation. The fetus has the enzyme activity needed for pregnenolone synthesis but has minimal ability to produce progesterone. High levels of circulating fetal progesterone are of placental origin so that circulating progesterone levels thus reflect placental function, not fetal wellbeing.

Progesterone can be metabolized to 17-hydroxyprogesterone (17-OHP), but relative efficiency of the enzymes favors progesterone production. 17-OHP levels do rise in the third trimester as progesterone levels peak. Additional progesterone metabolites, particularly 5-dihydroprogesterone (5-DHP) and its metabolite allopregnanolone, are also produced in the SynT at increased levels during gestation (Dombroski et al., 1997). These steroids have been hypothesized to play an endocrine role in fetal brain development and provide neuroprotection in the face of hypoxia (Pasca and Penn, 2010; Hirst et al., 2014).

Progesterone (da Fonseca et al., 2003) or a synthetic form of 17-OHP (Meis et al., 2003) is used therapeutically in gestation, as an adjunct for pregnancy maintenance after in vitro fertilization or in the second half of gestation for prevention of preterm delivery in women with a prior history of preterm birth (Di Renzo et al., 2012). Progesterone is required for the maintenance of pregnancy in part by means of its suppressant effect on uterine contractions (Csapo et al., 1973; Kallen, 2004; Ragusa et al., 2004). Progesterone inhibits genes that promote contractility (Mesiano et al., 2002) and has immunosuppressive activity that may promote uterine quiescence (Ragusa et al., 2004; Hardy et al., 2006). Progesterone also counteracts uterine estrogen effects. Unlike the drop in progesterone levels prior to labor seen in most mammals, there is no progesterone withdrawal per se that occurs before labor in women; however, modulation of progesterone receptor expression in combination with a shift in the progesterone to estrogen balance is presumed to play the same biological role. The relationship of therapeutic response to normal physiologic mechanisms at work in the maternal-fetal-placental unit is not yet understood.

Estrogens

Unlike the requirement for maternal precursors for progesterone production, estrogen production relies on fetal precursors. In pregnancy, estrogens are synthesized from C19 steroids (Siiteri and MacDonald, 1966), primarily from dehydroepiandrosterone sulfate (DHEA-S) made in the fetal adrenals. The fetal adrenals rapidly inactivate steroids through sulfatization. Pregnenolone is sulfated and converted to DHEA-S (Benirschke et al., 1956), which then may be hydroxylated in the fetal liver. These biologically inactive androgens are then transferred back to the placenta. Placental sulfatases rapidly cleave the sulfate, and placental 3β -hydroxysteroid dehydrogenase converts DHEA or hydroxylated DHEA to androstenedione or hydroxylated androstenediones, respectively. These androgens are then aromatized to estrone (E1),

• **Fig. 5.4** Basal Plate of the Human Placenta at Mid Gestation. A multinucleated layer of syncytiotrophoblasts (SynTs) covers the finger-like projections of chorionic villi. SynTs perform all of the transport functions of the placenta. A single cell layer of cytotrophoblasts (CTBs) sits just below the SynT layer and is referred to as villous CTB. These cells fuse with each other as they differentiate into SynTs. At the tips of anchoring villi sits a column of CTBs that are proliferative and that put out waves of invasive CTBs (extravillous trophoblasts) that help anchor the placenta to the uterus. Importantly, these also invade maternal spiral arterioles, where they replace the endothelial lining, induce the apoptotic death of surrounding smooth muscle cells, and transdifferentiate into an endothelialized cell type. This invasion typically courses through the extent of the uterine myometrium. CTBs can also invade veins but do not appear to remodel them. Additionally, maternal uterine immune cells, such as natural killer cells, appear to play an important role in enabling CTBs to invade the uterus and its vasculature. Finally, establishment of a receptive deciduum is also of critical importance for proper placental development and pregnancy success. (Adapted from Genbacev O, et al. *Dev Biol.* 2001 May 15;233[2]:526-36.)

16 α -OH estrone, or 15 α -OH estrone and then converted to estradiol (E2), estriol (E3), or estetrol (E4) respectively by placental 17 β -hydroxylation (Jameson et al., 1986; Morrish et al., 1987; Shi and Zhuang, 1993). E3 is the major estrogen of pregnancy with the majority secreted into the maternal compartment; E1 is the only estrogen preferentially secreted into the fetal compartment. Although maternal DHEA-S serves as 40% of the precursor for E2 synthesis, E3 and E4 are formed predominantly from fetal precursors because the maternal liver has limited 5 α -hydroxylation or 16 α -hydroxylation capabilities (Madden et al., 1978). E3 and E4 are thus indicators of fetal function (Tulchinsky et al., 1972), although neither is a clinically useful marker because of rapid shifts in circulating levels. The primary function of high E3 levels remains unclear, but it does increase uteroplacental blood flow (Resnik et al., 1974).

Estrogens influence uterine growth, blood flow, contractility, metabolism, and breast development (Branchaud et al., 1983). However, high estrogen levels are not apparently needed for pregnancy. Parturition can proceed in the absence of fetal and placental sulfatase (Bradshaw and Carr, 1986) or aromatase (Harada, 1993), although in the latter case both fetus and mother are virilized. In such pregnancies, there is still circulating estradiol. There are no reports of pregnancy without detectable estrogen levels, suggesting that a basal level of estrogen is likely required. Before parturition, an increase in the estrogen to progesterone ratio occurs within the intrauterine tissues and may increase prostaglandin (PG) and oxytocin (OT) activity. Steroid hormone production is

altered by trophic hormones and other factors, including hypothalamic-like releasing or inhibiting hormones. In turn, estrogens affect other endocrine systems (i.e., renin-angiotensin system) (Carr and Gant, 1983) and support organ maturation such as surfactant production in the lung (Parker et al., 1987).

Glucocorticoids

In addition to the sex steroids, circulating levels of glucocorticoids and mineralocorticoids are increased in pregnancy (Dorr et al., 1989). The placenta has the ability to produce cortisol and to convert it to inactive cortisone via 11 β -hydroxysteroid dehydrogenase type 2. This enzyme also converts maternal cortisol to cortisone at the placental interface. The primary role of this system appears to be to protect the fetus from elevated cortisol exposure, which may play a role in long-term reprogramming of the fetal HPA axis (Challis et al., 2001). Dual oxidative and reductive enzymatic activity regulates the balance between cortisol and cortisone (Pepe and Albrecht, 1995). In the placenta, oxidation of cortisol to cortisone predominates, whereas in the decidua, the reverse reaction dominates, potentially providing localized hormone exposure.

Pituitary-Like Hormones

A combination of pituitary-like growth hormones are required to support fetal growth while maintaining maternal metabolic homeostasis.

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is one of the first hormones of pregnancy, produced by trophoblasts even before placenta formation (Hay and Lopata, 1988) and is unique to human pregnancy (Maston and Ruvalo, 2002). After placentation, hCG is synthesized primarily by the SynT (Midgley, 1962) and passes into the maternal circulation via secretion into the intervillous space. hCG is a glycoprotein heterodimer (36 to 40 kDa) composed of α and β subunits encoded by genes on chromosome 6 and 19, respectively (Hussa, 1980; Fournier et al., 2015). The α subunit is homologous to pituitary thyroid-stimulating hormone (TSH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH), while the β subunit is homologous to LH. Intact hCG (i.e., having both α and β subunits) is required for hCG endocrine activities. Since it shares a receptor with LH, the LH chorionic gonadotrophin receptor (LHCGR), hCG mimics the function of LH, but the functions of LH and hCG are quantitatively different due to the longer half-life of hCG and its relative stability compared with the pulsatile release of pituitary LH (Muyan and Boime, 1997).

hCG maintains corpus luteal progesterone production until this function shifts to the maturing placenta. hCG peaks approximately 2 weeks after the shift of progesterone production from ovary to placenta, potentially minimizing the chance of loss of the progestational environment. hCG can be detected in human serum or urine within a week of conception and is the most frequently used biochemical marker for pregnancy. hCG doubling time may be used in early gestation to predict general pregnancy outcome. After hCG can first be detected, it increases with a doubling time averaging 2.11 days. It reaches peak levels of approximately 50 international units (IU)/mL at 9 to 10 weeks from the date of the last menstrual period, declining to 1 IU/mL by mid gestation (Osathanondh and Tulchinsky, 1980). An abnormally slow doubling time of hCG is considered to be a sign of a poor prognosis for pregnancy outcome, while rising hCG without detection of an intrauterine embryo suggests an ectopic pregnancy (Fritz and Guo, 1987).

In addition to corpus luteum maintenance, hCG has multiple additional activities that regulate placental structure and function. hCG acts as an autocrine signal in trophoblasts expressing LHCGR promoting the differentiation of SynTs, thus amplifying its own production since it is made primarily by these cells (Shi and Zhuang, 1993). Phosphorylation of the receptors via this pathway also decreases LHCGR expression in differentiating SynTs, thus completing a feedback loop (Pidoux et al., 2007). hCG may also have roles in endometrial angiogenesis, uterine quiescence, and immunotolerance to the fetus (Osathanondh and Tulchinsky, 1980; Fritz and Guo, 1987; Fournier et al., 2015). In addition, hCG can alter maternal TSH levels, elevating free thyroxine (T₄), although this increase does not appear to cause maternal hyperthyroidism (Challis et al., 2009).

Glycosylation state and subunit availability regulate hCG activity. A hyperglycosylated form (hCG-H) has been detected in early pregnancy, as well as in choriocarcinoma cells. hCG-H appears to enhance trophoblast invasion (Fournier et al., 2015) and thus may be a very early biomarker of placental invasion of the endometrium. A decreased level of hCG glycosylation in very early pregnancy has been correlated with early pregnancy loss (O'Connor et al., 1998; Kovalevskaya et al., 1999; Fournier et al., 2015). Isoform production may also regulate activity. β -Subunit production exceeds α -subunit production in early pregnancy, but this ratio rapidly shifts to α -subunit excess, increasing as gestation progresses; circulating hCG is mostly intact hCG or free α -hCG. It has been proposed

that ratios of hCG isoforms (intact hCG, independent subunits, and nicked breakdown products) present in maternal blood and urine might be useful for detection of pregnancy-related disorders since only intact hCG is fully active (Montagnana et al., 2011).

Local and systemic factors influence hCG production. Locally, its expression is regulated by a releasing factor, gonadotropin-releasing hormone (GnRH) 1 and 2 (Khodr and Siler-Khodr, 1978; Khodr and Siler-Khodr, 1980; Siler-Khodr and Grayson, 2001). Neurotransmitters (Shi and Zhuang, 1993), cyclic adenosine monophosphate (Jameson et al., 1986), epidermal growth factor (EGF) (Morrish et al., 1987), activin (Steele et al., 1993), cytokine (Wegmann and Guilbert, 1992), and PGs (Licht et al., 1993) regulate hCG production, as does hCG itself as noted previously. Each of these factors is produced by the placenta, as well as by other extraembryonic tissues. hCG alters placental steroidogenesis by stimulating both progesterone and estrogen formation. Estrogens inhibit GnRH stimulation of hCG (Branchaud et al., 1983), thereby completing a feedback axis in the placenta.

Human Chorionic Somatomammotropin

Human chorionic somatomammotropin (hCS), originally known as human placental lactogen (Higashi, 1961; Josimovich and Maclaren, 1962), has both growth hormone-like and lactogenic activity. hCS is detectable in extraembryonic tissues within 10 days of conception and in maternal serum by the third to fourth week of gestation. It is a single 191 amino acid nonglycosylated peptide chain with considerable homology to growth hormone (GH) (96%) and PRL (67%); it is transcribed from a gene cluster on chromosome 17 containing two genes for hCS, one hCS pseudogene and two GH genes (Rygaard et al., 1998; Handwerger and Freemark, 2000). SynTs produce hCS at a constant rate during gestation, thus hCS levels reflect total placental mass and gross placental function. By term, hCS is made at 1 gram per day, representing 10% of total placental protein synthesis.

hCS is considered one of the major diabetogenic factors of pregnancy, along with placental steroids, placental GH variant (hGH-V), and maternal cortisol. It is almost exclusively found in maternal rather than fetal circulation. This has led to the hypothesis that the primary role of hCS is to ensure adequate fetal nutrition because, in maternal circulation, it induces metabolic changes such as mobilization of fatty acids, insulin resistance, decreased utilization of glucose, and increased availability of amino acids through decreased maternal use of protein (Grumbach et al., 1968). Circulating maternal glucose and free fatty acids are thus increased. While glucose readily crosses the placenta, fatty acids cross slowly, thus biasing glucose delivery toward the fetus and use of fatty acids for maternal energy, especially during maternal fasting. Within the placenta, hCS may regulate insulin-like growth factor (IGF-1) (Kanda et al., 1998) and alter fetal growth through direct action on placental nutrient transport systems. In addition to its metabolic activity, the lactogenic activity of hCS may prepare the breast for lactation, working synergistically with PRL and steroids (Alsatt et al., 1998). Most recently, a role for hCS as a placental angiogenic factor has been suggested (Corbacho et al., 2002).

Placental Growth Hormone Variant

hGH-V is encoded in the same chromosome 17 gene cluster as hCS and pituitary GH. Two transcripts are generated from the hGH-V gene, a major form and an alternatively spliced version. Secreted hGH-V is translated from the major version and is produced in a highly bioactive 22 kD nonglycosylated form and to a lesser degree in a 25 kD glycosylated form (Alsatt et al., 1998).

Early in pregnancy, maternal pituitary GH is produced, but from 15 to 20 weeks' gestation to term hGH-V secretion increases, suppressing maternal GH. hGH-V peaks about a month before term delivery and disappears from maternal circulation immediately after delivery (Newbern and Freemark, 2011). hGH-V is not detected in the fetal circulation. Much like hCS, hGH-V modifies maternal metabolism to meet fetal needs. hGH-V primarily appears to control maternal IGF-1 production (Newbern and Freemark, 2011). In mice overexpressing hGH-V (not normally found in rodents), body weight was increased, IGF-1 levels were elevated, and insulin resistance developed, suggesting that hGH-V strongly contributes to the insulin resistance of pregnancy (Barbour et al., 2002) and increases the risk of gestational diabetes and other pregnancy-related pathologies. This risk is counterbalanced by placental lactogens, hCS and PRL, which induce increased insulin secretion by pancreatic β -cell expansion. hGH-V secretion is tonic, in contrast to pulsatile pituitary GH, and is not regulated by hypothalamic releasing factors (Newbern and Freemark, 2011). Secretion is inhibited by elevated glucose and mildly increased by hypoglycemia, creating a feedback loop that may ensure constant delivery of nutrients to the developing fetus.

Insulin-Like Growth Factors

IGF1 and IGF2, are the primary somatotrophs in gestation. IGFs are highly homologous single chain polypeptides with similarities to pro-insulin made in human placental tissues (Han and Carter, 2000). The majority of the components of the insulin/IGF system are found in the placenta (IGF1, IGF2, and the IGF-binding proteins [IGFBP] 1–6) (Forbes and Westwood, 2008) except insulin itself, although maternal insulin has profound indirect effects on fetal growth and wellbeing. hGH-V levels regulate placental IGF levels (Kanda et al., 1998), and IGFBPs are carrier proteins expressed in the human placenta that prevent IGF from degradation while blocking bioactivity (Hill et al., 1993; Han and Carter, 2000; Forbes et al., 2008). IGFBP1 is also produced by the decidua in large amounts. IGFBPs are themselves regulated by protease activity and through posttranslational modifications, adding a further layer of regulatory complexity.

IGF1 is expressed predominantly in SynT throughout gestation, with some CTB expression, while IGF2 is expressed only in CTB with a declining level across gestation (Hill et al., 1993; Han and Carter, 2000; Forbes and Westwood, 2008; Newbern and Freemark, 2011). At physiologic concentrations, both IGF1 and IGF2 bind to the IGF1 receptor (IGF1R). The localization of IGF1R shifts during gestation; initially it is predominantly expressed on SynTs (closer to the maternal circulation), and by term it is mainly expressed on the fetal CTB side, reflecting the shifting activity from maternal to fetal growth control (Forbes and Westwood, 2008). The IGF2 receptor (IGF2R; also known as the cation-independent mannose-6-phosphate receptor) controls extracellular IGF2 concentrations by mediating the endocytosis and degradation of IGF2, rather than by direct signaling via the receptor (Gicquel and Le Bouc, 2006). An additional receptor, possibly a variant of the insulin receptor, may mediate some of the fetal growth effects of IGF2 (Baker et al., 1993).

Information on the role of IGFs in fetal growth comes from genetic manipulation in mouse models as well as examination of human tissues, especially from fetal growth restricted pregnancies (Gicquel and Le Bouc, 2006). Disruption of mouse Insulin-like growth factor (*Igf1*), *Igf2*, or insulin-like growth factor 1 receptor (*Igf1r*) genes retards fetal growth (Baker et al., 1993), while disruption of *Igf2r* or overexpression of IGF2 enhances fetal growth

(Eggenschwiler et al., 1997). In humans, mutations in the *IGF1* or *IGF1R* genes are extremely rare, and no *IGF2* gene deletions have been reported (Gicquel and Le Bouc, 2006). However, *IGF2* is an imprinted gene normally expressed exclusively from the paternal allele in placenta and fetal tissues. Changes in *IGF2* expression because of abnormal imprinting have been linked to both overgrowth (Beckwith–Wiedemann syndrome) and growth retardation (Russel–Silver syndrome) (Gicquel and Le Bouc, 2006). Whether placentally derived IGFs, versus fetal IGFs, directly contribute to these fetal growth changes is uncertain since these factors also have paracrine effects in the placenta that determine nutrient transport and placental growth.

IGF1 can promote SynT differentiation, while IGF2 does not appear to have this function despite its very early placental expression. In vitro experiments suggest that placental mass is regulated directly by placental IGFs (Forbes et al., 2008); in vivo, loss of IGF2 reduces the placental surface area available for gas and nutrient exchange more than IGF1 loss. Both IGFs increase nutrient transport, especially of amino acids, which may be reflected in elevated fetal amino acids associated with gestational diabetes (Cetin et al., 2005; Forbes et al., 2008). IGFs may alter fetal growth through additional mechanisms since they potentiate EGF activity (Bhaumick et al., 1992), increase prolactin and progesterone production (Nestler, 1987; Kubota et al., 1991), and inhibit placental thromboxane production (Siler-Khodr et al., 1995).

Other Secreted Growth Factors

Platelet-derived growth factor A, transforming growth factor (TGF)- α , and TGF- β (Rappolee et al., 1988) expression in blastocysts appear to be involved in implantation. Other growth factors, including EGF, basic FGF, nerve growth factor, granulocyte colony-stimulating factor, and hepatocyte growth factor as well as growth factor receptors are expressed by the placenta and membranes at later gestation stages (Chegini and Rao, 1985; Stewart, 1996; Uehara and Kitamura, 1996; Morrish et al., 1998). The actions of many of these growth factors may be nonclassical autocrine actions. For example, EGF is made in SynTs, and EGF receptors on SynTs correlate with trophoblast differentiation rather than proliferation (Maruo and Mochizuki, 1987; Mitchell, 1987; Marzoni et al., 2005). Additional growth factor actions on placental development are under intensive investigation.

Inhibin and Activin

Inhibin and activin, an antagonist and agonist of pituitary FSH, respectively, are expressed by CTBs and fetal membranes (Petraglia et al., 1987b; Petraglia, 1997) while activin receptors are expressed in SynT (Florio et al., 2004a). Inhibin inhibits hCG and reduces progesterone production (Petraglia et al., 1987b), while activin has the opposite effect (Petraglia et al., 1989). Inhibin elevation is associated with fetal trisomy 21, while elevated activin is associated with PE and gestational diabetes (Florio et al., 2004a). Thus during pregnancy these hormones may serve as potential biomarkers of placental pathologies.

Proopiomelanocortin Hormones

Pituitary-like peptides derived from proopiomelanocortin (POMC), including adrenocorticotrophic hormone (ACTH), melanocyte-stimulating hormone, β -endorphins, and β -lipoproteins, as well as full length POMC itself, are found in the human placenta (Krieger, 1982; Raffin-Sanson et al., 1999). The processing of POMC in the placenta is different from in the pituitary: POMC is released largely intact from the placenta, while it is cleaved into

several peptide hormones in the nonpregnant state. While pituitary POMC-derived peptides respond to and regulate physiologic stress, placental POMC is not inhibited by glucocorticoids nor do circulating levels correlate with ACTH or cortisol levels, although they do correlate with corticotrophin-releasing hormone (CRH) levels (Raffin-Sanson et al., 1999). Chorionic CRH is produced by the placenta and stimulates the release of chorionic ACTH (see later) (Reis et al., 1999). The physiologic role of chorionic ACTH has not been defined, but it may affect placental cortisol production or maternal resistance of ACTH suppression by glucocorticoids.

Hypothalamic-Like Hormones

Every known hypothalamic releasing or inhibiting hormone has a placental analogue (Khodr and Siler-Khodr, 1978, 1980; Siler-Khodr, 1993; Siler-Khodr and Grayson, 2001). These hormones act in placental paracrine–autocrine regulatory networks that control release of placental endocrine hormones.

Gonadotropin-Releasing Hormone

In the placenta, chorionic GnRH, which regulates the paracrine axis, is important for early pregnancy maintenance, as well as regulating gonadal steroid production through stimulation of pituitary LH and FSH (Pawson et al., 2003). Two isoforms of GnRH (GnRH1 and GnRH2) are produced (Seeburg and Adelman, 1984; Siler-Khodr and Grayson, 2001; Sasaki and Norwitz, 2011). GnRH1 is encoded on chromosome 8 as a precursor protein that includes a signal sequence, the GnRH decapeptide, a processing sequence, and a GnRH-associated peptide (Cheng and Leung, 2005). GnRH2 is encoded on chromosome 20 and has 70% homology to GnRH1. GnRH1 and GnRH2 signal through the same G protein coupled receptor, GnRHR1, expressed in SynTs, but may activate different intracellular signaling pathways (Haning et al., 1982; Chou et al., 2003; Sasaki and Norwitz, 2011). Blocking GnRHs or GnRHR1 activity can lead to pregnancy failure (Das and Talwar, 1983; Jagannadha Rao et al., 1985; Sridaran, 1986; Kang et al., 1989), possibly through alteration of hCG and placental steroids, whose production and release they modulate (Siler-Khodr et al., 1986b). The release of placental GnRH1 is affected by cyclic adenosine monophosphate, PGs, epinephrine (Petraglia et al., 1987a), and inhibin (Higashi, 1961), while the expression of GnRHR1 is regulated by GnRH1, activin, and inhibin, creating a feedback loop (Sasaki and Norwitz, 2011).

Corticotrophin-Releasing Hormone and Urocortins

Chorionic CRH and CRH receptors are expressed in placenta and fetal membranes (Shibasaki et al., 1982; Frim et al., 1988; Riley and Challis, 1991; Florio et al., 2000). Urocortins, members of the CRH-hormone family, are also produced and bind to CRH receptors as well (Florio et al., 2004b). Early in gestation, CRH family members may promote immune tolerance (Makrigiannakis et al., 2004). As gestation progresses, CRH and urocortin levels rise peaking at term with delivery (Florio et al., 2004b). These hormones stimulate POMC-derived hormones, including ACTH and β -endorphinins, (Margioris et al., 1988; Florio et al., 2004b), as well as PG release, suggesting roles in parturition (Jones and Challis, 1989). CRH can also stimulate fetal adrenal estrogen and glucocorticoid production (Mesiano and Jaffe, 1997), which may contribute to the timing of parturition. Glucocorticoids can increase placental CRH expression (Jones et al., 1989), in contrast to glucocorticoid inhibition of CRH in the hypothalamus, creating a positive feedback loop that amplifies CRH activity (Nicholson and King, 2001). Because of its tight

association with delivery timing, CRH is often viewed as a *placental clock* (McLean and Smith, 2001) and may be biomarker of pregnancy pathology. In pregnancies complicated by hypertension, the maternal circulating levels of CRH are already elevated by 28 weeks of pregnancy whereas local urocortin levels may be decreased (Petraglia et al., 1996; Florio et al., 2004b). CRH has been proposed as a predictor for preterm delivery (Holzman et al., 2001; McLean and Smith, 2001), but significant clinical utility has not yet been demonstrated (McGrath and Smith, 2002; Smith and Nicholson, 2007).

Thyrotropin-Releasing Hormone

Chorionic thyrotropin-releasing hormone (Shambaugh et al., 1979) is made by the placenta and fetal membranes, but a clear role for either the mother or the fetus has not been identified. Pituitary TSH does not cross the placenta, nor does the placenta make thyroid hormone itself, but maternal T4 and triiodothyronine (T3) cross the placenta carried by placentally produced transthyretin (Landers et al., 2009; Li et al., 2012; Forhead and Fowden, 2014). The placental role in thyroid metabolism has been of considerable recent interest since thyroid disease is common in women of childbearing age and impacts pregnancy outcomes (Nathan and Sullivan, 2014). Early maternal hypothyroidism appears to be associated with lower intelligence quotient in offspring, but conflicting reports exist on the impact of maternal hypothyroidism after onset of fetal thyroid function in mid gestation (Chan et al., 2009; Nathan and Sullivan, 2014). Maternal T4 continues to cross from maternal to fetal circulation in the second and third trimesters; even fetuses with complete thyroid dysgenesis have 30%–50% normal T4 levels in cord blood (Vulsma et al., 1989). Placenta regulation of thyroid hormone transport and metabolism may play a critical role in fetal wellbeing, but the regulatory pathways remain to be defined.

Growth Hormone-Releasing Hormone, Somatostatin, and Ghrelin

Additional releasing factors are made in the CTB, including growth hormone-releasing hormone (Berry et al., 1992), somatostatin (Nishihira and Yagihashi, 1978), and ghrelin (Gualillo et al., 2001) and may regulate hGH-V production as well as placental differentiation (Fuglsang et al., 2005).

Leptin

Leptin is normally secreted by adipocytes and decreases food intake through hypothalamic actions, but in pregnancy, the placenta is the primary leptin source (Ashworth et al., 2000; Linnemann et al., 2001). The precise roles of leptin in the placenta, the mother, or the fetus are not known but may differ significantly from the nonpregnant state, as leptin levels in pregnancy do not correlate with body mass nor produce satiety (Henson and Castracane, 2000; Hauguel-de Mouzon et al., 2006). Increased leptin levels are seen in PE and gestational diabetes (Miehle et al., 2012; Tessier et al., 2013).

Oxytocin

OT is another hypothalamic hormone produced in the placenta and membranes (Gimpl and Fahrenholz, 2001). OT is a potent uterotonic hormone, used clinically to induce or speed labor. However, neither circulating maternal OT nor locally produced OT appears to increase markedly before labor; rather uterine response to OT is increased through increases in OT receptor (OTR) expression and function (Fuchs et al., 1995; Mitchell and

Chibbar, 1995). Progesterone suppresses OTR signaling during gestation (Gimpl and Fahrenholz, 2001), but a decline in progesterone activity at term (although not absolute progesterone levels in humans) increases OTR expression making the uterus more responsive to OT.

Additional Placental Secreted Factors

Vasoactive Peptides

The angiotensin–renin system has been described in the placenta and is thought to be a factor in the regulation of vascular tone in the placental bed. Multiple vasoactive peptides—VEGF, endothelin, angiotensin, arginine vasopressin, and atrial natriuretic peptide—and their receptors are placentally expressed (Myatt et al., 1992; Chao et al., 1993; Kingdom et al., 2000; VanWijk et al., 2000; Kaufmann et al., 2004). A balance of these factors is likely required for appropriate fetoplacental perfusion. For example, atrial natriuretic peptide inhibits the vasoconstrictive action of endothelin and angiotensin and induces vasodilatation in the uterus and the placenta.

Endogenous Opioid Peptides

Opioid peptides, enkephalins (Tan and Yu, 1981) and dynorphin (Lemaire et al., 1983), and their receptors are expressed in placenta, with an increase in placental receptors at term.

Cytokines

Cytokines—interferons, tumor necrosis factor- α (TNF- α), leukemia inhibitory factor, and interleukins (Chaouat et al., 2002; Kimber, 2005; Paulesu et al., 2005; Piccinni, 2005; Hauguel-de Mouzon and Guerre-Millo, 2006)—and their receptors are produced by the placenta, as well as by uterine endothelial cells and invading macrophages (Jokhi et al., 1997; Sel'kov et al., 2000; Piccinni, 2005; Varla-Leftherioti, 2005). Successful implantation requires a proinflammatory cytokine environment (Dealtry et al., 2000; Loke and King, 2000), while pregnancy maintenance requires cytokine expression that suppresses the maternal immune response (Keelan et al., 1999; Challis et al., 2009). Before parturition, this balance again shifts back to proinflammatory cytokines (Jokhi et al., 1997; Keelan et al., 1999; Sel'kov et al., 2000; Varla-Leftherioti, 2005). The balance of cytokines and related factors, either proinflammatory or antiinflammatory, may be a key trigger for preterm labor caused by intrauterine infection or other types of inflammation (Sel'kov et al., 2000; Challis et al., 2009). Cytokine expression also regulates trophoblastic and vascular placental function (Saito, 2001). Cytokines affect these activities by regulation of other cytokines, growth factors, hormones, and prostanoid production (Lundin-Schiller and Mitchell, 1991; Laham et al., 1997; Mohan et al., 2001).

Eicosanoids

Eicosanoids, such as thromboxanes (TXAs), PGs, and leukotrienes, are inflammatory mediators expressed in placenta that are derived from arachidonic acid (Harper et al., 1983; Majed and Khalil, 2012). Human term placentas convert arachidonic acid primarily to TXAs and the PGs PGE₂, PGF₂ α , and PGD₂ (Harper et al., 1983; Siler-Khodr et al., 1986a). Much like cytokines, they play a role in trophoblast implantation (Lewis, 1982) and in parturition (Challis and Patrick, 1980; Casey and MacDonald, 1988). After implantation, these factors, particularly prostacyclin (PGI₂) and PGE₂, appear to be vasoregulators of the fetal–placental unit (Challis and Patrick, 1980; Ylikorkala et al., 1983; Sorem and Siler-Khodr,

1995). PGI₂ is a potent vasodilator in placental vessels, an inhibitor of platelet aggregation, and a uterine relaxing factor; its loss has been implicated in PE. TXA₂ opposes PGI₂, and production is increased in PE; low-dose aspirin preferentially inhibits TXAs in the placenta and may decrease development of PE.

Immunologic Function

Throughout pregnancy the risk of fetal infection must be balanced against fetal rejection. This balance is maintained on both the maternal and fetal sides of the placenta. Unique features of the cells at the placental interface are required to allow the genetically distinct fetal “graft” to inhabit the maternal host. Placental trophoblast cells directly encounter maternal immune cells: SynT_s covering the placental villi are bathed in maternal blood and the invading trophoblasts exposed to the maternal decidua. Different strategies appear to be used at these sites to prevent destruction by cytotoxic maternal immune cells. For example, neither SynT_s nor invading trophoblasts express classic human leukocyte antigen (HLA)-A or HLA-B class Ia major histocompatibility complex antigens nor HLA class II antigens. However, invading trophoblasts do express nonclassic HLA-G and HLA-C, HLA types that can actually suppress immune responses, especially through leukocyte inhibitory receptors on uterine natural killer (NK) cells and macrophages. A balance of innate immunity and modulation of adaptive immune responses is required, and this balance shifts throughout gestation (Hunt et al., 2010; Christiansen, 2013).

The decidua is replete with innate immune cells including T cells, regulatory T cells, macrophages, dendritic cells, and uterine NK (uNK) cells. The best-studied subtype is the NK population. NK cells peak and constitute the largest leukocyte population in the early pregnant uterus, accounting for 60%–70% of total lymphocytes. These cells diminish in proportion as pregnancy proceeds. Despite being replete with cytotoxic perforin, granzymes A and B, and the natural cytotoxicity receptors (NKp30, NKp44, NKp46, NKG2D, NGK2B4, and LFA-1), these NK cells are tolerant cytokine-producing cells at the maternal–fetal interface (Kalkunte et al., 2008). The temporal occurrence around the SpAs and timed amplification of these specialized NK cells observed during the first trimester implicate their role in SpA remodeling. NK cell-deficient mice display abnormalities in decidual artery remodeling and trophoblast invasion, possibly because of a lack of uNK cell-derived interferon γ (Ashkar et al., 2000). Other studies have shown that uNK cells are a major source of VEGF-C, angiopoietins 1 and 2, and TGF- β 1 within the placental bed that decrease with gestational age (Lash et al., 2006). These observations implicate uNK cells in promoting angiogenesis. Recent studies suggest that VEGF-C may induce the noncytotoxic activity in maternal immune cells as well (Kalkunte et al., 2009). Additional molecules expressed on trophoblasts, such as members of the B7 family that alter lymphocyte activity and FasL, which interacts with Fas leukocyte receptors, may also modulate cytotoxicity in the placenta.

Both maternal macrophages and Hofbauer cells (macrophages in the villi that are derived from the fetus) are present in the placenta during pregnancy. These cells may prevent uterine infections or facilitate vascular remodeling and immune suppression (Nagamatsu and Schust, 2010b). Much like NK populations, alterations in macrophage activation, both maternal and fetal, have been linked to pregnancy complications such as IUGR, preterm birth, and PE (Nagamatsu and Schust, 2010a).

Maternal tolerance to fetal alloantigens was initially explored in the context of T-helper cells (Th)1/Th2 balance in mice, with

Th2 cells and cytokines proposed to predominate over Th1 cellular immune response under normal pregnancy. In human pregnancy, the role of specialized T lymphocytes, termed *regulatory T cells* (Tregs), in producing immune tolerance has emerged. Tregs are potent suppressors of T-cell-mediated inflammatory immune responses and prevent autoimmunity and allograft rejection. CD4+CD25+ Tregs are found in the decidua throughout pregnancy. Fetal-specific Tregs persist between pregnancies, and they accumulate and reexpand their population rapidly in subsequent pregnancies, potentially providing a persistent protective regulatory memory to fetal antigen (Rowe et al., 2012). The specific role of these Tregs in human pregnancy loss remains to be defined.

Immunosuppressive immune modulators are also highly expressed at the placental interface. Many of the endocrine factors produced by the placenta (progesterone, PGE2, and interleukins) as described above appear critical to maternal immune modulation. For example, the antiinflammatory cytokine interleukin (IL)-10 is expressed by human trophoblasts and Tregs, increasing across the first two trimesters and then declining before delivery. Low IL-10 expression has been linked to pregnancy loss and preterm delivery, as well as PE. However, how IL-10 protects the fetus is poorly understood. IL-10^{-/-} mice are fertile if maintained pathogen-free but are highly susceptible to complications from infection suggesting that IL-10 deficiency plus a “second hit” such as infection, environmental factors, or hormonal dysregulation may contribute to poor pregnancy outcomes (Thaxton and Sharma, 2010).

There is no generalized immunosuppression in pregnant women. Rather, there is a balance struck between specific types of immune suppression and activation. Indeed, cytokine production capacity is higher in pregnant than in nonpregnant women. It is the balance of proinflammatory to antiinflammatory cytokines that may determine outcome. When this balance is altered early in gestation, implantation could be affected, while immune alterations in late gestation may contribute to susceptibility to preterm birth, particularly in the face of an immune challenge. Similar shifts in the fetal immune response from tolerance to activation are being investigated across normal gestation (Mold et al., 2010). The role of placental immune activation in poor neonatal outcome, particularly in neurologic complications, has become an area of active study in the past decade (Kim et al., 2015a; Kim et al., 2015b). Defining and manipulating placental immune responses are key components of current efforts to improve pregnancy outcomes.

Fetal Programming

Complex yet intricate interactions between maternal and fetal systems promote fetal growth and normal pregnancy outcomes, interactions that must occur via the placenta. The placenta does not play a passive role as the interface between mother and fetus. Rather, it adapts to maternal status—nutrition, stress, environmental exposures—with altered vascularity and cellular composition and changes in endocrine and transport functions. Fetal genotype and fetal metabolic demands can also alter placental nutrient transfer and possibly other placental functions. Epidemiologic evidence first suggested that these complex interacting pathways alter the in utero environment in ways that lead to long-term changes in health and disease, particularly cardiovascular and metabolic disease (Barker and Osmond, 1986). How these interactions occur, as well as specific links between the in utero environment and later adult morbidities, is referred to as “fetal programming” or the “developmental origins of health and disease” (Fig. 5.5) (Burton et al., 2016).

Nutrition is the best-studied mechanism of fetal programming, although many other maternal and fetal programming events likely have long-term impacts (Fig. 5.6). Undernutrition can elicit placental and fetal adaptive responses that lead to local ischemia and metabolic, hormonal, and immune reprogramming, resulting in small for gestational age (SGA) fetuses. Maternal health and dietary status, exposure to environmental factors, uteroplacental blood flow, placental transfer, and fetal genetic and epigenetic responses likely all contribute to in utero fetal programming. Adult diseases such as coronary heart disorders, hypertension, atherosclerosis, type 2 diabetes, insulin resistance, respiratory distress, altered cell-mediated immunity, cancer, and even psychiatric disorders are being linked to fetal programming in utero (Sallout and Walker, 2003). In addition to maternal predisposing factors, cytokines, hormones, growth factors, and the intrauterine immune milieu also contribute to in utero programming. Therefore a healthy mother with healthy placentation is critical to healthy fetal outcomes.

Regulation of Placental Function

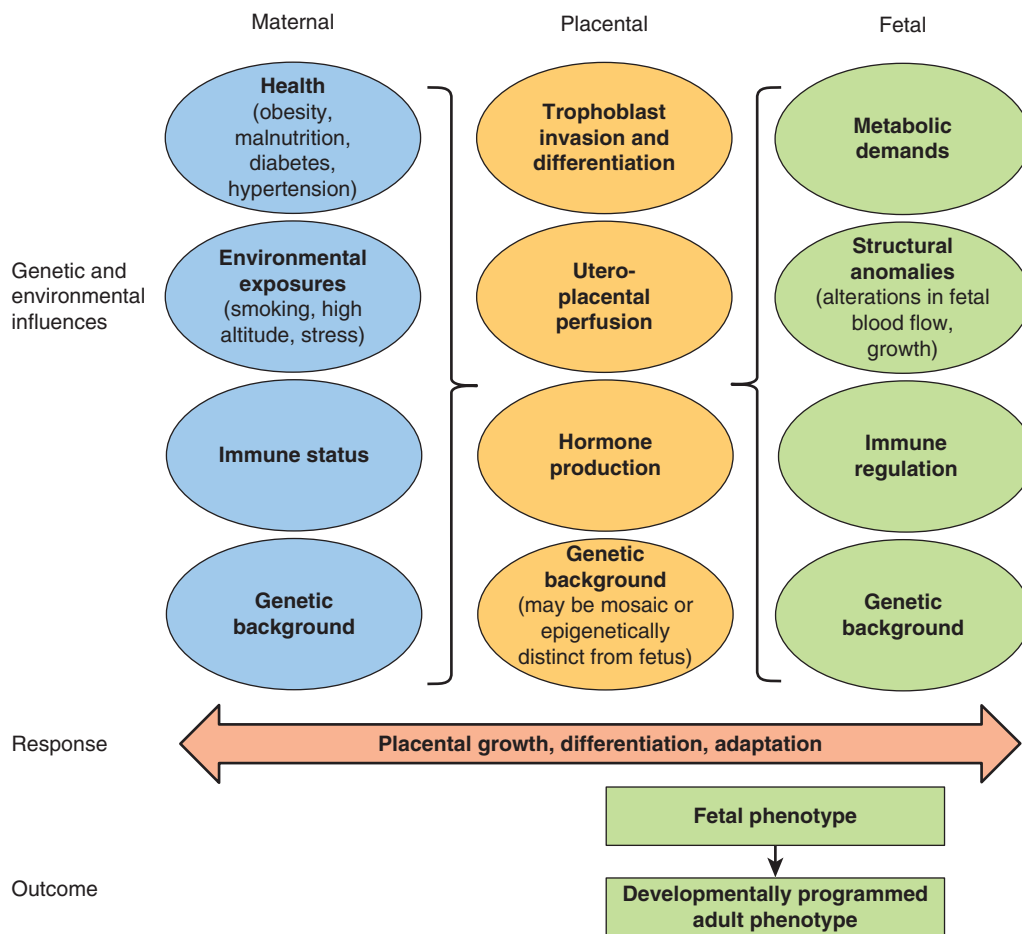

While it is now recognized that placental function can have lifelong impacts on health, the molecular mechanisms that underlie this complex signal integration and regulation are not yet well understood but are critically important to human disease. An understanding of the molecular mechanisms underlying the placental integration of maternal and fetal information that results in fetal programming may suggest new ways to manage pregnancy complications that lead to fetal growth failure and long-term alterations to health. To date, the two best documented forms of placental regulation are (1) signal integration thorough specific signaling cascades and (2) epigenetic modifications of placental gene expression.

Nutrient-Sensing Signaling Pathways

Multiple signaling molecules are expressed in SynT cells that are responsive to nutrient supply, including mechanistic target of rapamycin (mTOR), adenosine monophosphate-activated protein kinase, and glycogen synthase-3 (see Fig. 5.6). Emerging evidence suggests that mTOR may be a key component of the placental nutrient-sensing signaling pathway (Jansson and Powell, 2013; Dimasuay et al., 2016). mTOR is a serine/threonine-specific protein kinase belonging to the family of phosphatidylinositol-3 kinase (PI3K)-related kinases. mTOR regulates cellular metabolism, growth, and proliferation by targeting and signaling through two protein complexes, mammalian target of rapamycin complex (mTORC1) and mTORC2. Both hypoxia and limited nutrient supply result in the mTORC1 inhibition seen in placentas of IUGR fetuses (Roos et al., 2007; Kavitha et al., 2014). In the case of maternal obesity and enhanced nutrition, mTORC1 appears to be activated. mTOR expression in turn regulates nutrient transporter trafficking, particularly amino acid transporters. Recent experiments in mice suggest that the maternal and the fetal genotype of the upstream regulator of mTOR, PI3K, both influence placental function, nutrient delivery, and maternal physiology (Sferruzzi-Perri et al., 2016). While the regulatory details of this pathway need to be elucidated in humans, regulating components of the mTOR pathway might provide novel treatments for disorders of fetal growth (Jansson and Powell, 2007).

Epigenetic Regulation in the Placenta

The placenta has unique epigenetic features that may make it particularly responsive to its environment. Epigenetic regulation

• **Fig. 5.5** Fetal Programming. Maternal and fetal health alter placental function, which in turn influences fetal adaptations. Dietary status, exposure to environmental factors, uteroplacental blood flow, placental transfer, and genetic and epigenetic changes contribute to in utero fetal programming.

of gene expression allows for heritable changes that are mediated independently of changes in DNA sequences themselves. Gene expression is largely determined by the accessibility of DNA to transcription factors, accessibility that is controlled by a variety of epigenetic mechanisms: methylation of DNA promoter regions, histone modifications, genomic imprinting, and expression of noncoding ribonucleic acids (RNAs) such as microRNA (miRNA). Since these alterations are not encoded in DNA, epigenetic changes can occur in response to the cellular environment. In utero changes in the epigenome have been linked to poor pregnancy outcomes, although the causal relationships remain unclear (Januar et al., 2015).

Massive epigenetic reprogramming with loss of DNA methylation occurs just after fertilization and before implantation. The placenta and other extraembryonic tissue remain hypomethylated, even though methylation increases with cellular differentiation so that even at term, the placenta is the most hypomethylated human tissue (Bianco-Miotto et al., 2016). Within the placenta, the various cell types have distinct methylation profiles. Nutritional components, such as folate, can alter placental and fetal methylation patterns (Jansson and Powell, 2007). Placental methylation changes have been linked to PE, IUGR, and preterm birth (Januar et al., 2015; Bianco-Miotto et al., 2016).

Methylation changes also contribute to genomic imprinting, in which an allele is silenced in a specific parent-of-origin manner.

Placental genomic imprinting is distinct from somatic imprinting, with most imprinted placental genes impacting fetal and/or placental growth or maternal preparation for care of offspring. Most of what is known about placental gene imprinting comes from studies on the IGF pathway in mouse, described above. Paternally expressed imprinted genes, such as *IGF2*, promote placental and fetal growth while maternally expressed ones, such as *IGF-2R*, suppress growth (Gicquel and Le Bouc, 2006). However, recent human studies suggest significant species specificity of imprinting, emphasizing the need for large-scale human placental studies to better define the role of this epigenetic mechanism in human pregnancy (Monk, 2015).

An additional layer of epigenetic regulation may be added by miRNAs, the small noncoding RNA gene products that regulate gene expression through repression of messenger RNA (mRNA) translation or mRNA decay (Mouillet et al., 2015). At least 500 miRNA species are expressed in the placenta, and those expressed in trophoblasts can be detected in maternal circulation (Chim et al., 2008) (Fig. 5.7). The functions of some of these miRNAs are starting to be decoded. For example, miR-675 is an miRNA embedded in the first exon of H19, a highly expressed large intergenic noncoding RNA. miR-675 is expressed only in the placenta when placental growth is slowing in the second half of gestation. Loss of H19 and thus miR-675 results in placental overgrowth, while overexpression of the miRNA results in reduced proliferation (Keniry et al., 2012).

• **Fig. 5.6** Placenta as a Nutrient Sensor. The role of the placenta in maternal–fetal resource allocation has been hypothesized to be a critical element of fetal programming (Jansson et al., 2013; Sferruzzi-Perri and Camm, 2016). Maternal and fetal genotype influence signaling pathways (i.e., the phosphoinositol 3-kinase/mechanistic target of rapamycin [*mTOR*] pathway) in the placenta that balance maternal environmental status and fetal demands. When the maternal nutrient supply is altered, the placenta responds to maternal signals to match fetal growth to the nutrient supply. The placental alterations are thus central to the long-term health of the fetus. *IGFs*, Insulin-like growth factors; *IGF-1*, insulin-like growth factor-1.

It is notable that epigenetic mechanisms used by the placenta are most similar to those seen in tumorigenesis, reflecting their invasive similarities. Large-scale patterns of hypomethylation, as well as site-specific hypermethylation of tumor suppressor genes often seen in cancers, occur in the placenta. In addition, some miRNAs that have been implicated in regulating uterine invasion are associated with malignancies when reactivated outside of the placental context (Mouillet et al., 2015). Given the limited invasive potential of the placenta under normal circumstances, there is likely to be an additional layer of regulation controlling the placental epigenetic response to both intrinsic and environmental cues.

Placental Diseases

Understanding placental dysfunction and disease during pregnancy is critical to improving neonatal outcomes. Healthy development of the placenta requires efficient metabolic, immune, hormonal, and vascular adaptation by the maternal system as well as the fetus. Abnormal placentation and placental infections can lead to PE, growth retardation, or preterm birth, which can have a lifelong bearing on health. Most major obstetric syndromes originate in early gestation because of abnormal trophoblast invasion or immune dysregulation but present clinically in late gestation. Maternal factors such as ascending infections, obesity, hypertension, diabetes, and environmental exposures also contribute to placental dysfunction.

Placental Disorders of Pregnancy

Preeclampsia

Maternal hypertension affects 5%–10% of human pregnancies, mainly due to PE (Ghulmiyyah and Sibai, 2012). PE is clinically associated with maternal symptoms of hypertension, proteinuria, and glomeruloendotheliosis; it can progress to eclampsia resulting in seizure, coma, and maternal death. The most common fetal complication is growth restriction (Srinivas et al., 2009). Early onset (<24 weeks' gestation) carries a greatly increased risk of IUGR. PE resolves only with delivery of the fetus and placenta. The maternal symptoms are mediated mainly by secreted placental factors, while the fetal symptoms result from impaired placental perfusion. Abnormal remodeling of SpAs and shallow trophoblast invasion are two hallmark features of PE (Brosens et al., 2011), but the etiology of this failure to invade remains unclear; endothelial dysfunction is a key component, and both fetal and maternal factors are thought to contribute. Poor placental perfusion may cause release of circulating factors leading to maternal symptoms, which then exacerbate placental failure and impaired fetal growth.

Despite limited mechanistic understanding of placental pathology leading to PE, several pathways are consistently implicated in this disease. Angiogenic and antiangiogenic factors, excessive complement cascade activation, and immune intolerance may all play a role. In normal pregnancy, angiogenic factors including VEGF and circulating PlGF steadily increase in the first and second trimesters,

• **Fig. 5.7** Placental Products Circulate in Maternal Blood During Gestation. The placental syncytiotrophoblasts produce and secrete extracellular vesicles of various sizes, shapes, and functions into the maternal circulation in both healthy and compromised pregnancies. The function and cargo of these vesicles is not yet completely defined but likely plays a role in maternal–fetal cross talk between cells during pregnancy. Circulating placental products may also provide biomarkers for placental function and pathologies. Exosomes are constitutively secreted products of the endosomal pathway that carry proteins, micro ribonucleic acid (RNA) and messenger RNA that can modulate maternal cell functions, including immune and endothelial responses. Microvesicles and apoptotic bodies are larger vesicles produced by direct budding of the plasma membrane following alterations in cellular conditions (oxygen tension, glucose, or calcium level changes) or as part of apoptosis, respectively. These vesicles may carry unsorted protein and nucleic acid cargo picked up from the cell cytosol. They may have a proinflammatory role in pregnancy. Circulatory cell-free DNA can be up to 13% of cell-free DNA in maternal circulation. Circulatory cell-free DNA is fragmented and significantly smaller than maternal fragments, allowing fragment size and sequence to be used to distinguish fetal from maternal origin. *mRNA*, Messenger ribonucleic acid; *miRNA*, micro RNA; *nm*, nanometers.

peak at 29 to 32 weeks, and decline thereafter. However, free VEGF remains low and unchanged during this window. Reduced placental expression of VEGF and PlGF is consistently observed in PE. Furthermore, PE is frequently accompanied by enhanced placental expression and free circulation of the soluble fms-like tyrosine kinase-1 (sFlt-1), which binds to and inactivates VEGF and PlGF (Levine et al., 2004a; Romero et al., 2008). Soluble endoglin, which enhances sFlt-1 activity, is also elevated in PE (Levine et al., 2004a; Venkatesha et al., 2006). Excessive complement cascade activation and immune activation may also contribute to PE, although whether it is a cause or effect of the pathology is unclear (Lynch et al., 2008). Altered regulatory T-cell function may alter trophoblast interaction with the uterine lining, and increased villous turnover from placental damage may increase maternal immune system response to circulating placental debris (Laresgoiti-Servitje et al., 2010).

Intrauterine Growth Restriction

IUGR or fetal growth restriction designates a fetus that has not reached its growth potential; it can be caused by fetal, placental, or maternal factors. Disparities between fetal nutritional or

respiratory demands and placental supply can result in impaired fetal growth. PE is a frequent cause of IUGR, but placental surface area reduction with decreased villi and fetal capillaries can be seen in IUGR alone, suggesting distinctive disease etiologies (Daayana et al., 2004; Srinivas et al., 2009). Chromosomal abnormalities (aneuploidy, partial deletions, and gene mutation, particularly on the gene for IGFs), congenital abnormalities, multiple gestation, and infections can also result in IUGR. IUGR may result in an SGA newborn. Mortality and morbidity are increased in SGA infants compared with those who are appropriate for gestational age. At birth, SGA infants may have impaired thermoregulation; poor cardiopulmonary transition with perinatal asphyxia, pulmonary hypertension, hypoglycemia, polycythemia, and hyperviscosity; impaired cellular immune function; and increased risk for perinatal mortality. In childhood, having been SGA increases the risk of neurodevelopmental impairments, and in adulthood, cardiovascular and metabolic disease risks are elevated (Sallout and Walker, 2003).

Preterm Birth

Infants born before the 37th week of gestation are considered premature, and their care places an enormous burden on the

healthcare infrastructure. Preterm infants face an increased risk of lifelong disabilities such as mental retardation, learning and behavioral problems, autism, cerebral palsy, chronic lung diseases, vision and hearing loss, and an increased risk for diabetes, hypertension, and heart disease in adulthood. In countries such as the United States, preterm birth accounts for approximately 10%–13% of all deliveries (Goldenberg et al., 2008). Despite improvements in our understanding of the risk factors associated with preterm delivery, the rate of prematurity has risen over the past two decades, due in large part to an increase in the rate of indicated preterm deliveries (Goldenberg et al., 2008). In the United States, iatrogenic delivery is responsible for almost half the births that occur between 28 and 37 weeks of gestation, primarily because of placental pathologies such as PE or IUGR. The majority of spontaneous preterm deliveries are due to preterm labor. Other factors leading to spontaneous premature birth are preterm premature rupture of membranes, cervical incompetence, and antepartum bleeding. Additional risk factors for preterm birth include stress, occupational fatigue, uterine distention by polyhydramnios or multifetal gestation, systemic infection such as periodontal disease, intrauterine placental pathology such as abruption, vaginal bleeding, smoking, substance abuse, maternal age (<18 or >40 years), obesity, diabetes, thrombophilia, ethnicity, anemia, and fetal factors such as congenital anomalies and growth restriction.

There is increasing evidence that approximately 50% of preterm births are associated with infection of the decidua, amnion, or chorion and amniotic fluid caused by either systemic or ascending genital tract infection (Goldenberg et al., 2008). Both clinical and subclinical chorioamnionitis are implicated in preterm birth. Maternal or fetal inflammatory responses to chorioamnionitic infection can trigger preterm birth (Romero et al., 2014). Activated neutrophils and macrophages and the release of cytokines IL-1 β , IL-6, IL-8, TNF- α , and G-CSF can lead to an enhanced cascade of signaling activity, causing release of PGs and expression of various MMPs of fetal membranes and the cervix. Elevated levels of TNF- α and apoptosis are associated with term premature rupture of membranes. Noninfection-related inflammation caused by placental insufficiency and apoptosis can also cause preterm birth. In addition to augmented inflammatory responses to infections, pathogenic microbes (e.g., *Staphylococcus*, *Streptococcus*, *Bacteroides*, and *Pseudomonas* spp.) are thought to directly degrade fetal membranes by releasing proteases, collagenases, and elastases, producing phospholipase A2, and releasing endotoxin that stimulates uterine contractions and causes preterm birth (Slattery and Morrison, 2002).

Interaction between the maternal HPA axis as a result of major maternal physical or psychological stress may also alter the normal placental production of HPA-like hormones, including increased production of CRH, which leads to increased fetal ACTH and cortisol production. Premature activation of the fetal HPA axis can eventually stimulate PG production, ultimately resulting in parturition. In addition, activation of the HPA axis promotes increases in estrogens, decreased progesterone, and OTR expression, further enhancing myometrial activation and preterm birth (Jones and Challis, 1989; Mesiano and Jaffe, 1997).

Gestational Diabetes

Impaired maternal glucose tolerance during pregnancy results in GDM. Impaired placental function may alter hCS production, and in turn, hyperglycemia can impair placental development, growth, and nutrient transport (Araujo et al., 2015). Remarkably, GDM can be associated with either IUGR or, more commonly, with fetal overgrowth (Sibley et al., 2005; Jansson et al., 2006). Placental integration of multiple signals including glucose levels,

intrinsic genetic susceptibility, and fetal demands may be a critical regulator of this fetal growth outcome (Sibley et al., 2005).

Central Nervous System Injury

Both acute and chronic placental dysfunction are linked to adverse neurologic outcomes in fetuses and neonates. Acute mechanical disruptions of placental function (umbilical cord occlusion or placental abruption) can result in severe neurologic hypoxic–ischemic damage before or during delivery but are relatively rare events. More commonly, chronic placental vascular lesions (chronic villitis, fetal thrombotic vasculopathy, or infection-associated fetal vasculitis) are correlated with neurologic injury, including cerebral palsy (Redline, 2005). Almost 90% of term infants with neonatal encephalopathy and brain injury have placental lesions noted postdelivery (Wintermark et al., 2010), although the high frequency of placental lesions in apparently neurologically intact newborns makes interpretation complex (Lachapelle et al., 2015; Redline, 2015). Preterm birth is an independent risk factor for neurologic injury, but chorioamnionitis, which frequently causes preterm delivery, is also associated with brain injury and increased risk of cerebral palsy, particularly when funisitis or severe fetal inflammation is present (Leviton et al., 1999; Romero et al., 2014; Kim et al., 2015a). IUGR infants are also at significantly increased risk of neurodevelopmental impairments (Redline et al., 2007; Apel-Sarid et al., 2010).

Evaluation of Placental Dysfunction

Until recently, placental assessment was performed almost exclusively after delivery, using traditional anatomic pathology techniques. While significant correlations have been described between specific pathologic lesions and neonatal outcomes, our understanding of how and when these lesions develop during gestation and ultimately lead to poor outcomes remains limited. There has been a recent resurgence of interest in developing advanced tools to investigate placental function during gestation, particularly following the launch of the “Human Placenta Project” by the Eunice Kennedy Shriver National Institutes of Child Health and Disease (Guttmacher et al., 2014; Guttmacher and Spong, 2015). In addition to promoting the development of new advanced imaging techniques (Andescavage et al., 2015; Siauve et al., 2015) and biomarker methods for measuring placental function (Cuffe et al., 2017), there has been a renewed interest in standardizing placental histopathologic classification and diagnosis. In 2014 an international group of placental pathologists met in Amsterdam to establish consensus guidelines for placental examination and classification of lesions (Khong et al., 2016), and these are summarized in Table 5.1.

Placental Histopathology

Direct examination of the placenta after birth can give some clues to the timing and extent of important adverse prenatal or neonatal events. Some disorders are readily apparent in the delivery room (listeria lesions, placental abruption associated with large clots, abnormal cord insertion), and others require more detailed gross and microscopic examination. In a high-risk delivery service, approximately 50% of placentas qualify for pathologic examination (Curtin et al., 2007).

The majority of placental lesions described by pathologists involve either vascular or immunologic/infectious processes (Table 5.1). Vascular processes can be further localized as maternal or fetal lesions (Fig. 5.8, villous maternal stromal-vascular lesions versus fetal-vascular lesions), potentially providing clues to both the underlying etiology of the lesion and its implications for maternal

• **Fig. 5.8** Histopathologic Sites of Action of Major Placental Disease Processes. (Modified from Redline RW. The clinical implications of placental diagnoses. *Semin Perinatol.* 2015;39:2–8.)

or fetal death. Immune processes likewise can be subdivided into chronic or acute infections and also distinguished from inflammatory processes associated with immune activation without infection (see Fig. 5.8, chronic villitis). Links have been made between each major pathologic lesion type and different pregnancy complications (Table 5.2).

Placental Imaging

Ultrasound (US) imaging remains the standard imaging method used for placental evaluation during pregnancy because of its availability, safety, and relatively low cost. However, US evaluation of placental anatomy can be limited by placental implantation site, maternal body habitus, and amniotic fluid volume, and US-detected lesions correlate poorly with postnatal histopathology (Moran et al., 2011). As a primary screening tool, placental US has proven very useful, but its use for functional placental assessment that can predict which pregnancies are at risk of later placental compromise is limited.

The placenta may be visible on US as early as 5 weeks' gestation (Wong et al., 2009). It becomes readily visible by 15 weeks' gestation by US and undergoes progressive increases in thickness and diameter as well as changes in echogenicity and shape (Moran et al., 2011). Both increased and decreased placental size are associated with abnormal development and risk of fetal complications. Many placental lesions can be seen by US as pregnancy progresses. Some, such as placental lakes, which are anechoic regions of low maternal blood flow, are very common but appear to be of limited clinical significance. Others, including echogenic areas of infarct, may be significant when large or centrally located. Placental calcifications increase across gestation. There appears to be an association between early development of calcifications and poor placental function, but use of early, high-grade calcification to predict pregnancy outcome has proved unreliable (Moran et al., 2011). Doppler

velocimetry is used in conjunction with anatomic US to functionally assess placental blood flow (Abramowicz and Sheiner, 2008). Fetal villous vascular damage results in high resistance in the umbilical artery (UA) circulation, and chronic fetal hypoxia decreases umbilical venous flow. Loss of UA end-diastolic flow is associated with severe IUGR and indicative of significant fetal compromise. Monitoring of placental blood flow allows detection of high resistance and poor circulation within the placenta but is usually apparent only when significant fetal compromise has already occurred. Additional US measures that may be more predictive of placental compromise, such as 3-dimensional placental volumes and vascularization indices (Moran et al., 2011), as well as new elastography and higher resolution US techniques, are under investigation.

Magnetic resonance imaging (MRI) is increasingly being used for anatomic placental evaluation, and advanced functional techniques may yield information on oxygenation, vascularization, and metabolism (Andescavage et al., 2015; Siauve et al., 2015). MRI benefits from having multiplanar images in a wider field of view, as well as having higher spatial and temporal resolution when compared with US. It is currently used primarily to assess fetal structural anomalies and, more recently, for improved detection of placenta accreta and other invasive placental anomalies (Lam et al., 2002). Precise quantitation of placental volume is more readily performed using MRI than US and may allow earlier prediction of fetal growth retardation based on small placental size (Derwig et al., 2011; Andescavage et al., 2015). Use of standard MRI gadolinium-based contrast agents has been limited due to fetal safety concerns, but new agents are being developed. Placental application of noncontrast functional MRI methods, including diffusion-weighted imaging and diffusion tensor imaging, are being investigated along with methods that rely on endogenous contrast agents, such as hemoglobin-based detection of oxygen level changes measured by blood-oxygen level-dependent MRI (Andescavage

TABLE 5.2 Common Placental Causes of Specific Adverse Pregnancy Outcomes

1. Fetal Growth Restriction
Maternal stromal-vascular lesions: global/partial vascular malperfusion with accelerated villous maturation
Fetal stromal-vascular lesions: developmental lesions (superficial implantation), global/partial vascular malperfusion (fetal thrombotic vasculopathy)
Villitis of unknown etiology
2. Spontaneous Preterm Birth
Maternal inflammatory response: acute chorioamnionitis
Maternal vascular lesions: mild global/partial vascular malperfusion with accelerated villous maturation
Acute marginal placental abruption
3. Preterm Fetal Death
Maternal stromal-vascular lesions: global/partial vascular malperfusion with accelerated villous maturation
Fetal global/partial vascular malperfusion (cord accidents/obstruction)
Placental abruption
4. Term Fetal Death
Fetal stromal-vascular lesions: developmental lesions (delayed villous maturation), global/partial vascular malperfusion (cord accidents/obstruction)
Placental abruption
Fetomaternal hemorrhage
5. Term Neurologic Injury
Fetal stromal-vascular lesions: global/partial vascular malperfusion (fetal thrombotic vasculopathy or cord occlusion)
Chronic villitis of unknown etiology with obliterative fetal vasculopathy
Acute chorioamnionitis with severe fetal inflammatory response
Presence of multiple placental lesions

Modified from Redline RW. Classification of placental lesions. *Am J Obstet Gynecol*. 2015 Oct;213(4 Suppl):S21-8.

et al., 2015; Siauve et al., 2015). Use of placental MRI for real-time assessments is likely to provide new information about placental vascular development and function, as well as new diagnostic tools for use in high-risk pregnancies.

Serum Biomarkers of Placental Disease

A major goal of pregnancy screening is to identify women early in gestation who will go on to develop placenta-mediated complications that threaten either fetal or maternal health so that targeted early therapies can be provided. Detection of factors released by the placenta into maternal circulation that predict disease is a longstanding area of investigation. In addition to physiologic secretion of placental factors into maternal circulation, cellular stress (i.e., oxidative, hypoxic, or inflammatory stress) can lead to increased villous trophoblast turnover with release of placental vesicles and cellular debris into the circulation (Cuffe et al., 2017). Maternal serum analytes, circulating cell-free DNA, and extracellular vesicle contents derived from the placenta are under investigation as potential biomarkers of placental dysfunction.

Serum Analytes

Maternal serum screening has been applied successfully in the identification of fetuses at increased risk of aneuploidy or structural anomalies (open neural tube defects, abdominal wall defects). The association is less clear between pregnancies at risk of placental dysfunction and abnormal values for the most common first and

second trimester serum screening markers: alpha fetoprotein, hCG, unconjugated estriol (uE₃), inhibin-A, and pregnancy-associated plasma protein-A (PAPP-A). Both single serum analyte abnormalities and combinations have been assessed for their value as biomarkers of specific pregnancy complications, with limited success (Gagnon et al., 2008). For example, higher levels of second trimester inhibin-A levels are associated with PE, although no predictive cutoff level has been identified. Elevated inhibin-A in combination with UA Doppler abnormality, however, may be strongly predictive of PE (Ay et al., 2005). Likewise, extensive studies of low PPAP-A and UA Doppler changes suggest an association with fetal growth restriction and PE (Pilalis et al., 2007). Some alterations of these maternal serum markers have been associated with specific pathologies linked to poor placental function, but the strongest associations are serum marker abnormalities and a generalized increased risk of third trimester fetal death (Gagnon et al., 2008). Increased surveillance or treatment of these pregnancies has not yet shown clinical benefit.

Additional maternal serum biomarkers of placental dysfunction, particularly in PE, include elevated circulating sFlt-1 and reduced PlGF. Syncytial stress leads to placental secretion of these and other angiogenic factors (Cuffe et al., 2017). A recent metaanalysis suggested that the diagnostic accuracy of maternal sFlt-1/PlGF for early onset PE is high, but false positives and false negatives are both greater than 15%, limiting the utility of this ratio as a broad clinical screening tool (Liu et al., 2015).

Circulating Cell-Free Fetal DNA

Direct measurement of DNA found in maternal serum has become possible in the past decade. Continuous turnover of placental villous trophoblasts releases placental microparticles and freely circulating nucleic acids (see Fig. 5.7). These fragments are called fetal but actually originate from the placenta (Taglauer et al., 2014). Noninvasive prenatal screening for aneuploidies and genetic mutations using circulating cell-free fetal DNA (cffDNA) screening from maternal serum has rapidly gained popularity in the past 5 years. Confined placental mosaicism with a normal fetal karyotype can confound these screening results, but the high sensitivity and specificity of these tests combined with their limited risk compared with chorionic villous sampling or amniocentesis have lead to their rapid clinical adoption. Total cffDNA levels, rather than specific cffDNAs, may also be useful biomarkers for placental health and function. cffDNA is increased in PE, both before and during the development of clinical symptoms, likely because of increased trophoblast apoptosis associated with oxidative stress (Levine et al., 2004b). High concentrations of cffDNA are also associated with increased preterm birth risk (Farina et al., 2005). Cell-free RNA and miRNAs have also been found in maternal circulation, and their utility as biomarkers is actively being assessed.

Extracellular Vesicles

Multiple types and sizes of vesicles are shed by the placenta in both normal and compromised pregnancies (see Fig. 5.7), but the amounts and contents vary with placental health (Cuffe et al., 2017). Exosomes are a subtype of extracellular vesicle derived from endosomes that carry proteins and RNAs and that are released by exocytosis into the extracellular space. Exosomes play a significant role in intercellular signaling in multiple systems, and their role in pregnancy has garnered intense interest in the past few years (Mitchell et al., 2015). Placentally derived exosomes carry SynT specific proteins, including placental alkaline phosphatase and the miRNAs from H19 described previously, allowing their identification as placental vesicles in maternal circulation. Their release is regulated

by multiple environmental factors including oxygen tension and glucose concentrations, making them particularly appealing as reporters of placental function. Exosomes mediate communication between the placenta and maternal immune cells, and widespread placental–maternal cellular communication using this mechanism has been proposed. There is a general increase in placental exosomes

in maternal circulation across gestation, and these levels may vary with placental pathology; the vesicle contents may also reflect pathology, such as decreased cell fusion proteins in exosomes from preeclamptic placentas (Mitchell et al., 2015). As placental exosome biology becomes better defined, use of exosomes as biomarkers of placental function is an exciting possibility.

Summary

The placenta is a complex organ that develops from many cell types to form a sophisticated interface between mother and fetus that integrates intrinsic and extrinsic signals to optimize fetal development. The consequences of impaired placental function have

lifelong impact not only on individual offspring but potentially on multiple generations, effected by epigenetic changes. Understanding and optimizing placental health is critical, not just to newborns but also to improving health outcomes for the entire population.

6

Abnormalities of Fetal Growth

REBECCA SIMMONS

KEY POINTS

- Customized fetal growth charts remain controversial.
- The major determinant of intrauterine growth is the placental supply of nutrients to the fetus.
- Fetal factors restricting intrauterine growth include fetal gender, familial genetic inheritance, and chromosomal abnormalities or dysmorphic syndromes.
- Fetal growth differs for women of diverse ethnicities, with Latina and white women having higher rates of large for gestational age (LGA) infants and African-American and South Asian women having a higher incidence of small for gestational age (SGA) infants.
- Impaired fetal growth is linked to the later development of diseases such as type 2 diabetes and heart disease.

Normal fetal growth is determined by a number of factors, including genetic potential, the ability of the mother to provide sufficient nutrients, the ability of the placenta to transfer nutrients, and intrauterine hormones and growth factors. The pattern of normal fetal growth involves rapid increases in fetal weight, length, and head circumference during the last half of gestation. During the last trimester, the human fetus accumulates significant amounts of fat. The birthweight for gestational measurements among populations has been shown to increase over time, and thus standards for normal fetal growth require periodic re-evaluation for clinical relevance. These increases in birthweight for gestational age over time are attributed to improvements in living conditions and maternal nutrition and changes in obstetric management. Variations in fetal growth have been identified in diverse populations and are associated with geographic locations (sea level versus high altitude), populations (white, African-American, Latino), maternal constitutional factors, parity, maternal nutrition, fetal gender, and multiple gestations. In this chapter, we discuss these factors in greater detail and critically review the long-term effects of abnormal fetal growth.

Defining Fetal Growth

The duration of pregnancy is an integral component of prenatal growth assessment, and all currently prevailing definitions of fetal growth are gestational age (GA) specific. Assessing the GA accurately, however, can be challenging, and any error in dating will lead to misclassification of the infant, which can have significant clinical implications. In many instances, the method of GA determination has contributed to variations in the GA specific reference growth

curves. For example, some nomograms are based on approximating the GA to the nearest week, whereas others use the completed weeks. The birthweight charts are also affected by other variables that may limit their reliability. Many of these factors, such as fetal gender, race, parity, birth order, parental size, and altitude, contribute to the normal biologic variations in human fetal growth.

There is continuing controversy on whether the reference growth charts should be customized by multiple variables or developed from the whole population. The customized approach predicts the optimal growth in an individual pregnancy and therefore specifically defines suboptimal growth for that pregnancy. However, it has been argued that such an approach may lead to a profusion of standards and may not contribute to improving the outcome of small for gestational age (SGA) infants. In recognition of the utility of a national standard, a population-based reference chart for fetal growth was developed from all the singleton births (over 3 million) in the United States in 1991 (Alexander et al., 1999). More recently, a similar national population-based fetal growth chart, which is also sex specific, has been developed in Italy. In a multicenter cross-sectional study, 8070 ultrasonographic examinations from low-risk singleton pregnancies between 16 and 40 weeks' gestation were used to develop growth curves based on biparietal diameter (BPD), head circumference (HC), abdominal circumference (AC), and femur length (FL). Quantile regression was used to examine the impact of fetal sex across the biometric percentiles of the fetal measurements considered together with parents' height, weight, parity, and race (Rizzo et al., 2016) (Fig. 6.1).

There is insufficient evidence about whether one approach is superior to the other in improving the perinatal outcome.

There is no universal agreement on the classification of a SGA infant. Various definitions appear in the medical literature, making comparisons between studies difficult. Additionally, investigators have shown that the prevalence of fetal growth restriction varies according to the fetal growth curve used (Alexander et al., 1996). The most common definition of SGA refers to a weight below the 10th percentile for GA or birthweight less than two standard deviations from the mean. Some investigators use measurements below the third percentile to define SGA. However, these definitions do not make a distinction between those infants who are constitutionally small, those who are growth restricted and small, and those who are not small but growth restricted relative to their potential. For example, as many as 70 percent of fetuses who weigh below the 10th percentile for GA at birth are small simply because of constitutional factors such as female sex or maternal ethnicity, parity, or body mass index (BMI); they are not at high risk of perinatal mortality or morbidity. In contrast, true fetal growth

• **Fig. 6.1** Comparison of the 5th (bottom line), 50th (middle line), and 95th (top line) centiles of the biometric measurements between male (blue line) and female sex (green dotted line) in a fetus with a paternal height of 180 cm, maternal height of 160 cm, maternal weight of 60 kg, mother nulliparous, and of Caucasian race. (A) Biparietal diameter. (B) Head circumference. (C) Abdominal circumference. (D) Femur length. AC, Abdominal circumference; BPD, biparietal diameter; FL, femur length; HC, head circumference. (Data from Rizzo G, Prefumo F, Ferrazzi E, et al. The effect of fetal sex on customized fetal growth charts. *J Matern Fetal Neonatal Med.* 2016;29:3768–3775.)

restriction is associated with numerous perinatal morbidities. This has clinical relevance to perinatologists and neonatologists, as many of the tiniest premature neonates in the neonatal intensive care units are probably growth restricted. McIntire and colleagues (1999) reported a “threshold” of increased adverse outcomes in infants born with measurements below the third percentile and suggested that this level of restriction represents a clinically relevant measurement. Other researchers have found higher rates of neonatal complications when the 15th percentile of birthweight is used as a cutoff level (Seeds and Peng, 1998).

There is an important distinction in identifying the fetus that suffers from intrauterine growth restriction (IUGR) and the fetus that is constitutionally small (SGA). IUGR refers to a condition

in which a fetus is unable to achieve its genetically determined potential size and represents a deviation and a reduction in the expected fetal growth pattern. IUGR complicates about 5%–8% of all pregnancies and 38%–80% of all low birth weight (LBW) neonates. This discrepancy underscores the fact that no uniform definition of IUGR exists. Even when a normal intrauterine growth pattern is established for a population, somewhat arbitrary criteria are used to define growth restriction.

Patterns of Altered Growth

Neonates with IUGR can be classified as demonstrating either symmetric or asymmetric growth. Infants with symmetric IUGR

have reduced weight, length, and head circumference at birth. Weight is affected (and then length) in infants with asymmetric growth restriction, with a relatively normal head circumference or “head-sparing” growth pattern. In general, factors intrinsic to the fetus cause symmetric IUGR, whereas maternal medical conditions such as preeclampsia, chronic hypertension, and uterine anomalies cause asymmetric IUGR. Asymmetric fetal growth patterns generally develop during the third trimester, a period of rapid fetal growth. However, now that fetal surveillance is more common, asymmetric growth restriction is often diagnosed in the second trimester.

Fetal Causes of Growth Restriction

Factors that are well recognized to limit the growth of both the fetal brain and body include chromosomal anomalies (e.g., trisomies), congenital infections (toxoplasmosis, rubella, cytomegalovirus, and herpes simplex [TORCH]), malaria, HIV, and parvovirus, skeletal dysplasias, and some inborn errors of metabolism. Cardiac and renal structural anomalies are common conditions associated with SGA. These conditions restrict fetal growth primarily by impaired cell proliferation. Recognized causes of IUGR are listed in Table 6.1. In one large population-based study, the frequency of IUGR among infants with congenital malformations was 22%. The majority of the infants affected had chromosomal abnormalities. Other studies have similarly found that fetal growth restriction is more common among infants with malformations. Fetal gender also influences size, with male infants showing greater intrauterine growth than female infants (Glinianaia et al., 2000; Skjaerven et al., 2000; Thomas et al., 2000).

TABLE 6.1 Causes of Intrauterine Growth Restriction

| | |
|---|--|
| Genetic | Inheritance, chromosomal abnormalities, fetal gender |
| Maternal constitutional effects | Low maternal prepregnancy weight, low pregnancy weight gain, ethnicity, socioeconomic status, history of IUGR |
| Nutrition | Low prepregnancy weight (body mass index), low pregnancy weight gain, malnutrition (macronutrients, micronutrients), maternal anemia |
| Infections | TORCH infections |
| Decreased O ₂ -carrying capacity | High altitude, maternal congenital heart disease, hemoglobinopathies, chronic anemia, maternal asthma |
| Uterine/placental anatomy | Abnormal uterine anatomy, uterine fibroid, vascular abnormalities (single umbilical artery, velamentous umbilical cord insertion, twin-twin transfusion), placenta previa, placental abruption |
| Uterine/placental function | Maternal vasculitis (system lupus erythematosus), decreased uteroplacental perfusion, maternal illness (preeclampsia, chronic hypertension, diabetes, renal disease) |
| Toxins | Tobacco, ethanol, lead, arsenic |

IUGR, Intrauterine growth restriction; TORCH, toxoplasmosis, rubella, cytomegalovirus, syphilis.

Placental Causes of Growth Restriction

In mammals, the major determinant of intrauterine growth is the placental supply of nutrients to the fetus (Fowden et al., 2006). Indeed, in many species, fetal weight near term is positively correlated to placental weight, as a proxy measure of the surface area for maternofetal transport of nutrients. Fetal weight near term is positively correlated to placental weight, and the nutrient transfer capacity of the placenta depends on its size, morphology, blood flow, and transporter abundance (Fowden et al., 2006). In addition, placental synthesis and metabolism of key nutrients and hormones influence the rate of fetal growth (Fowden and Forhead, 2004). Changes in any of these placental factors can, therefore, affect intrauterine growth. However, the fetus is not just a passive recipient of nutrients from the placenta. The fetal genome exerts a significant acquisitive drive for maternal nutrients through adaptations in the placenta, particularly when the potential for fetoplacental growth is compromised.

Placental maturation at the end of pregnancy is associated with an increase in substrate transfer, a slowing (but not cessation) of placental growth, and a plateau in fetal growth near term (Fox, 1997). Fetal size and placental growth are directly related, and placentas from pregnancies yielding growth-restricted infants demonstrate a higher incidence of smallness and abnormality than those from pregnancies with appropriately grown infants. The difference in size is seen even in a comparison of placentas associated with growth-restricted infants and those associated with appropriate for gestational age (AGA) infants of the same birthweight (Heinonen et al., 2001). Clinical conditions associated with reduced placental size (and subsequent reduced fetal weight) include maternal vascular disease, uterine anomalies (fibroids, abnormal uterine anatomy), placental infarctions, unusual cord insertions, and abnormalities of placentation.

Multiple gestations are associated with greater risk for fetal growth restriction. The higher risk stems from crowding and from abnormalities with placentation, vascular communications, and umbilical cord insertions. Divergence in fetal growth appears from about 30 to 32 weeks in twin gestation compared with singleton pregnancies (Alexander et al., 1996; Glinianaia et al., 2000; Skjaerven et al., 2000), although this may occur earlier in gestation (Devoe and Ware, 1995). Abnormalities in placentation are also more common with multiple gestations (Benirschke, 1995). Monochorionic twins can share placental vascular communication (twin-twin transfusion), leading to fetal growth restriction during gestation. Fetal “competition” for placental transfer of nutrients raises the incidence of growth restriction and discordance in growth between fetuses. The rate of birthweights less than the fifth percentile is higher in monochorionic twins. Placental growth is restricted in utero because of limitation in space, leading to a higher incidence of placenta previa in multiple-gestation pregnancies. Additionally, abnormalities in cord insertions (marginal and velamentous cord insertions) and occurrence of a single umbilical artery are more frequently found in multiple gestations.

Investigators have shown an effect of altitude on fetal growth, with infants born at high altitudes having lower birthweights (Moore et al., 2011). Differences in fetal growth are detected from about 25 weeks’ gestation, when pregnant women reside at altitudes greater than 4000 meters. In these high-altitude pregnancies, the AC is most affected (Krampl et al., 2000). Interestingly, investigators have shown that adaptation to high altitude during pregnancy is also possible. Tibetan infants have higher birthweights than infants

of more recent ethnic Chinese immigrants living at the same high-altitude (2700–4700 meters) region of Tibet (Moore et al., 2001). Tibetan infants also have less IUGR than infants born to more recent immigrants to the area.

Maternal Causes of Growth Restriction

Maternal health conditions associated with chronic decreases in uteroplacental blood flow (maternal vascular diseases, preeclampsia, hypertension, maternal smoking) are associated with poor fetal growth and nutrition. Preeclampsia has been shown to be associated with fetal growth restriction (Spinillo et al., 1994; Xiong et al., 1999; Ødegård et al., 2000). Investigators have shown that the extent of growth restriction correlates with the severity and the onset during pregnancy of the preeclampsia. Ødegård et al. (2000) showed that fetuses exposed to preeclampsia from early in pregnancy had the most serious growth restriction, and more than half of these infants were born SGA. Chronic maternal diseases (cardiac, renal) may decrease the normal uteroplacental blood flow to the fetus and thus may also be associated with poor fetal growth (Spinillo et al., 1994).

Maternal constitutional factors have a significant effect on fetal growth. Maternal weight (prepregnancy), maternal stature, and maternal weight gain during pregnancy are directly associated with maternal nutrition and correlate with fetal growth (Goldenberg et al., 1997; Clausson et al., 1998; Mongelli and Gardosi, 2000; Doctor et al., 2001). Numerous studies show that these findings are often confounded by highly associated cultural and socioeconomic factors. The woman with a previous SGA infant has a higher risk of a subsequent small infant (Robinson et al., 2000). Investigators have shown a higher incidence of SGA infants to be associated with lower levels of maternal education (Clausson et al., 1998). Parity of the mother also affects fetal size, nulliparous women having a higher incidence of SGA infants (Cnattingius et al., 1998). A large population-based study in Sweden found that women who were older than 30 years, were nulliparous, or had hypertensive disease were at increased risk of preterm and term growth-restricted infants.

Studies have shown differential fetal growth for women of diverse ethnicities, with Latina and white women having higher rates of large for gestational age (LGA) infants and African-American and South Asian women having a higher incidence of SGA infants (Fuentes-Afflick et al., 1998; Alexander et al., 1999; Collins and David, 2009). These gender and ethnic differences in birthweight become pronounced after 30 weeks' gestation (Thomas et al., 2000). Investigators in California have shown that US-born black women have higher rates of prematurity and LBW infants than foreign-born black women. Other researchers have found that even among women with very low risk of LBW infants (married, age 20–34 years, 13 or more years of education, adequate prenatal care, and absence of maternal health risk factors and of tobacco or alcohol use), the risk of delivering an SGA infant is still higher for African-American women than for white women (Collins and David, 2009; Alexander et al., 1999). It is unclear whether these differences in fetal growth are due to inherent differences or to differential exposure to environmental factors, including stress.

Maternal nutrition significantly impacts fetal growth, primarily in developing countries (Godfrey et al., 1996; Neggers et al., 1997; Robinson et al., 2000; Doctor et al., 2001; Zeitlin et al., 2001). Although numerous factors interact with and affect fetal development, maternal malnutrition is assumed to be a major cause of IUGR in developing countries.

Teen pregnancy represents a special condition in which fetal weight is highly influenced by maternal nutrition. Teen mothers (<15 years) have been shown to have a higher risk for delivering a growth-restricted infant (Ghidini, 1996). Teen pregnancies are complicated by the additional nutritional needs of a pregnant mother, who is still actively growing, as well as by socioeconomic status of pregnant teens in developed countries (Scholl and Hediger, 1995).

The effects of micronutrients on pregnancy outcomes and fetal growth have been less well studied. Maternal intake of certain micronutrients has been found to affect fetal growth. Zinc deficiency has been associated with fetal growth restriction as well as other abnormalities, such as infertility and spontaneous abortion (Jameson, 1993; Shah and Sachdev, 2001). Additionally, dietary intake of vitamin C during early pregnancy has been shown to be associated with an increase in birthweight (Mathews et al., 1999). Other clinicians have shown strong associations between maternal intake of folate and iron and infant and placental weights (Godfrey et al., 1996). In developing countries, the effects of nutritional deficiencies during pregnancy are more prevalent and easier to detect. Rao and colleagues (2001) have estimated that one-third of infants in India are born weighing less than 2500 g, mainly because of maternal malnutrition. These investigators have shown significant associations between infant birthweight and maternal intake of milk, leafy greens, fruits, and folate during pregnancy.

Although toxins such as cigarette smoke and alcohol have a direct effect on placental function, they may also affect fetal growth through an associated compromise in maternal nutrition. Other environmental toxins (lead, arsenic, mercury) are associated with IUGR and are believed to affect fetal growth by entering the food chain and depleting body stores of iron, vitamin C, and possibly other nutrients (Iyengar and Nair, 2000; Srivastava et al., 2001).

Numerous studies have shown associations between birthweight and maternal intake of macronutrients and micronutrients, but the effects of nutritional supplements used during pregnancy on fetal growth are equivocal (de Onis et al., 1998; Jackson and Robinson, 2001; Rush, 2001; Say et al., 2003). This is underscored by the results of a large double-blind, randomized controlled trial including 1426 pregnancies that was carried out in rural Burkina Faso (Roberfroid, 2008). Pregnant women were randomly assigned to receive either iron and folic acid or the UNICEF/WHO/UNU international multiple micronutrient preparation (UNIMMAP) daily until 3 months after delivery. Birthweight was only increased by 52 grams and birth length by 3.6 mm. Unexpectedly, the risk of perinatal death was marginally, though significantly, increased in the UNIMMAP group (odds ratio: 1.78; 95% confidence interval: 0.95, 3.32; $P = .07$).

Maternal socioeconomic status and ethnicity have also been identified as risk factors for IUGR and poor health outcomes in infants, in both developing and developed countries (Wilcox et al., 1995). In the United States, low levels of maternal and paternal education, certain maternal and paternal occupations, and low family income are associated with lower birthweights in children of African-American, Hispanic, and white women (Balcazar, 1994; Parker et al., 1994). In a large population-based study from Sweden, investigators have similarly shown a higher incidence of fetal growth restriction in association with low maternal education (Clausson et al., 1998). The incidence of IUGR is also higher in women without medical insurance (Collins and Butler, 1997; Frisbie et al., 1997; Thomas et al., 2000). Interestingly, Mexican-born immigrants in California have better perinatal outcomes (including birthweight) than both African Americans and US-born women of Mexican

descent (Fuentes-Afflick et al., 1998). The reasons for this apparent paradox are unclear, but one postulate is the tendency of recent immigrants to maintain the favorable nutritional and behavioral characteristics of their country of origin (Guendelman and English, 1995). These studies support the speculation that the differences in fetal growth between groups do not reflect inherent differences in fetal growth but rather stem from inequalities in nutrition, health care, and other environmental factors (Keirse, 2000; Kramer et al., 2000).

Finally, multiple studies have shown an association between assisted reproductive technology (ART) and low birth weight (Hansen and Bower, 2014). Recent metaanalyses of infants born following ART compared with non-ART singletons show increases in low birth weight, preterm birth, and small for gestational age (SGA). Although there have been small reductions in recent data, odds associated with these outcomes are still higher for ART singletons. It is generally thought that both ART procedures and underlying infertility contribute to these increased risks.

Maternal Smoking

Cigarette smoking is consistently found to adversely affect intrauterine growth in all studies in which this factor is considered. In developed countries, cigarette smoking is the single most important cause of poor fetal growth (Kramer et al., 2000). The incidence of IUGR in smokers is estimated to be 3–4.5 times higher than in nonsmokers (Nordentoft et al., 1996; Bernstein et al., 2000). Lieberman and associates (1994) report that cigarette smoking also appears to have a dose-dependent effect on the incidence of IUGR, with this effect being seen especially with heavy smoking and smoking during the third trimester. These investigators have shown that if women stop smoking during the third trimester, their infants' birthweights are indistinguishable from those of infants born to the normal population. Other researchers have shown that even a reduction in smoking is associated with improved fetal growth (Li et al., 1993; Walsh et al., 2001). Numerous potential causes of the effects of smoking on fetal growth have been suggested, including direct effects of nicotine on placental vasoconstriction, decreased uterine blood flow, higher levels of fetal carboxyhemoglobin, fetal hypoxia, adverse maternal nutritional intake, and altered maternal and placental metabolism (Pastrakuljic et al., 1999; Andres and Day, 2000).

Short-Term Outcomes of Fetal Growth Restriction

IUGR alters many physiologic and metabolic functions in the fetus and neonate that result in a number of morbidities. A large cohort study of 37,377 pregnancies found a fivefold to sixfold greater risk of perinatal death for both preterm and term fetuses with IUGR (Cnattingius et al., 1998; Mongelli and Gardosi, 2000; Lackman et al., 2001). Regarding predictive factors for perinatal mortality in preterm IUGR fetuses, of all the antenatal factors examined, only oligohydramnios and abnormal umbilical artery Dopplers with absent or reversed diastolic flow were predictive of perinatal mortality (Scifres et al., 2009). Although the growth-restricted fetus may show symmetric or asymmetric growth at birth, it is unclear whether the proportionality of the fetus with IUGR truly affects outcomes or is related to the timing or the severity of the insult. Lin and colleagues (1991) found that symmetric IUGR resulted in higher levels of prematurity and higher

rates of neonatal morbidity. In contrast, Villar and associates (1990) have shown that infants with asymmetric IUGR have higher morbidity rates at birth. They found that infants with low ponderal index measurements (which they defined as weight/length³) had higher risk for low Apgar scores, long hospitalization, hypoglycemia, and asphyxia at birth than infants with symmetric IUGR. Other investigators propose that IUGR represents a continuum, with asymmetric IUGR occurring as the severity of the growth retardation increases. Data also suggest that the more severe the growth restriction, the worse the neonatal outcomes, including risk of stillbirth, fetal distress, neonatal hypoglycemia, hypocalcemia, polycythemia, low Apgar scores, and mortality (Kramer et al., 1990; Spinillo et al., 1995).

Fetal growth restriction is associated with intrauterine demise. Almost 40% of term stillbirths and 63% of preterm stillbirths are SGA (Mongelli and Gardosi, 2000). Both short-term and long-term effects of abnormalities in SGA fetuses have been described. Perinatal mortality for intrauterine SGA infants is higher overall than that for appropriately grown term and preterm infants (Clausson et al., 1998). The risk of perinatal death is estimated to be fivefold to sixfold greater for both preterm and term fetuses with IUGR (Lackman et al., 2001). Overall, intrauterine death, perinatal asphyxia, and congenital anomalies are the main contributing factors to the higher mortality rate in SGA infants. The effects of acute fetal hypoxia may be superimposed on chronic fetal hypoxia, and placental insufficiency may be an important etiologic factor in these outcomes. Investigators have described higher incidences of low Apgar scores, umbilical artery acidosis, need for intubation at delivery, seizures on the first day of life, and sepsis in SGA infants (Villar et al., 1990; McIntire et al., 1999). The incidence of adverse perinatal effects correlates with the severity of the growth restriction, the highest rates of respiratory distress syndrome, metabolic abnormalities, and sepsis being found in the most severely growth-restricted infants (Spinillo et al., 1995).

Preterm infants with growth abnormalities have a much higher risk of adverse outcomes. Preterm SGA infants have a higher incidence of a number of complications, including sepsis, severe intraventricular hemorrhage, respiratory distress syndrome, necrotizing enterocolitis, cholestatic jaundice, and death, than normally grown preterm infants (Gortner et al., 1999; McIntire et al., 1999; Simchen et al., 2000; Robinson and Ehrenkranz, 2008). Additionally, SGA infants have higher incidence of chronic lung disease at corrected gestational ages of 28 days and 36 weeks (Bose et al., 2009; Mestan and Steinhorn, 2011; Morsing et al., 2012; Briana and Malamitsi-Puchner, 2013).

Neonatal hypoglycemia and hypothermia occur more frequently in growth-restricted infants (Doctor et al., 2001). These metabolic abnormalities presumably result from decreased glycogen stores, inadequate lipid stores, and impaired gluconeogenesis in the growth-restricted neonate. Growth-restricted neonates have inadequate fuel stores and are at increased risk for hypoglycemia during fasting, and these risks are increased in preterm SGA infants. Infants with IUGR also have a higher incidence of hypocalcemia, the incidence correlating strongly with the severity of the growth restriction (Spinillo et al., 1995).

Developmental Outcomes of Fetal Growth Restriction: Early Childhood

Neurologic outcomes, including intellectual and neurologic function, are affected by growth restriction. Overall, neurologic morbidity

is higher for SGA infants than for AGA infants. Even without identified perinatal events, SGA infants have a higher incidence of long-term neurologic or developmental handicaps (Walker and Marlow, 2008; Batalle et al., 2012; Llurba et al., 2013; Lohaugen et al., 2013; Longo et al., 2013; Von Beckerath et al., 2013). SGA infants born at term appear to have double or triple the risk for cerebral palsy, between 1–2 per 1000 live births and 2–6 per 1000 live births (Goldenberg et al., 1998). The rate of cerebral palsy is also higher in preterm growth-restricted infants than in preterm infants with appropriate fetal growth (Gray et al., 2001). At 7 years of age, children whose birth was associated with hypoxia-related factors had a higher risk for adverse neurologic outcomes. Infants with symmetric IUGR (or perhaps more severe restriction) were at higher risk than infants with asymmetric IUGR. Other researchers have shown higher rates of learning deficits, lower IQ scores, and increased behavioral problems in children with a history of fetal growth restriction, even at 9–11 years of age (Low et al., 1992).

Long-Term Consequences of Fetal Growth Restriction: the Developmental Origins of Adult Disease

Programming

The period from conception to birth is a time of rapid growth, cellular replication and differentiation, and functional maturation of organ systems. These processes are very sensitive to alterations in the intrauterine milieu. *Programming* describes the mechanisms whereby a stimulus or insult at a critical period of development has lasting or lifelong effects. The “thrifty phenotype” hypothesis proposes that the fetus adapts to an adverse intrauterine milieu by optimizing the use of a reduced nutrient supply to ensure survival, but because this adaptation favors the development of certain organs over that of others, it leads to persistent alterations in the growth and function of developing tissues (Hales and Barker, 1992). Also, although the adaptations may aid in survival of the fetus, they become a liability in situations of nutritional abundance.

Epidemiology

It has been recognized for over 80 years that the early environment in which a child grows and develops can have long-term effects on subsequent health and survival (Kermack, 1934). The landmark cohort study of 300,000 men by Ravelli and colleagues (1976) showed that men who were exposed in utero to the effects of the Dutch famine of 1944 and 1945 during the first half of gestation had significantly higher obesity rates at age 19 years. Subsequent studies demonstrated a relation between low birth weight and the later development of cardiovascular disease (Barker et al., 1989) and impaired glucose tolerance (Fall et al., 1995) in men in England. Those men who were smallest at birth (2500 g) were nearly seven times more likely to have impaired glucose tolerance or type 2 diabetes than those who were largest at birth. Barker and colleagues (1993) also found a similar relationship between lower birthweight and higher systolic blood pressure and triglyceride levels.

Valdez and associates (1994) observed a similar association between birthweight and subsequent glucose intolerance, hypertension, and hyperlipidemia in a study of young adult Mexican-American and non-Hispanic white men and women participants

in the San Antonio Heart Study. Normotensive, nondiabetic individuals whose birthweights were in the lowest tertile had significantly higher rates of insulin resistance, obesity, and hypertension than subjects whose birthweights were normal. In the Pima Indians, a population with extraordinarily high rates of type 2 diabetes, McCance and coworkers (1994) found that the development of diabetes in the offspring was related to both extremes of birthweight. In their study, the prevalence of diabetes in subjects 20–39 years old was 30% for those weighing less than 2500 g at birth, 17% for those weighing 2500–4499 g, and 32% for those weighing 4500 g or more. The risk for development of type 2 diabetes was nearly fourfold higher for those whose birthweight was less than 2500 g. Other studies of populations in the United States (Curhan et al., 1996), Sweden (Lithell et al., 1996; McKeigue et al., 1998), France (Leger et al., 1997; Jaquet et al., 2000), Norway (Egeland et al., 2000), and Finland (Forsen et al., 2000) have all demonstrated a significant correlation between low birth weight and the later development of adult diseases.

Studies controlling for the confounding factors of socioeconomic status and lifestyle have further strengthened the association between low birth weight and higher risk of coronary heart disease, stroke, and type 2 diabetes in adulthood. In 1976, the Nurses' Health Study was initiated, and a large cohort of American women born from 1921 to 1946 was established. The association between low birth weight and increased risks of coronary heart disease, stroke, and type 2 diabetes remained strong even after adjustment for lifestyle factors such as smoking, physical activity, occupation, income, dietary habits, and childhood socioeconomic status (Rich-Edwards et al., 1999).

The Role of Catch-Up Growth

Many studies have suggested that the associations between birth size with later disease can be modified by BMI in childhood. The highest risk for the development of type 2 diabetes is among adults who were born small and become overweight during childhood (Eriksson et al., 2000). Insulin resistance is most prominent in Indian children who were SGA at birth but had a high fat mass at 8 years of age (Bavdekar et al., 1999). Similar findings were reported in 10-year-old children in the United Kingdom (Whincup et al., 1997). In a Finnish cohort, adult hypertension was associated with both lower birthweight and accelerated growth in the first 7 years of life. In contrast, in two preliminary studies from the United Kingdom, catch-up growth in the first 6 months of life was not clearly related to blood pressure in young adulthood, although birthweight was (McCarthy et al., 2001).

Interpretation of the findings of these studies is complicated by the vague definitions of *catch-up growth*. The term, which can encompass either the first 6–12 months only or as much as the first 2 years after birth, usually refers to realignment of one's genetic growth potential after IUGR. This definition allows for fetal growth restriction at any birthweight; even large fetuses can be growth restricted in relation to their genetic potential. However, postnatal factors can obviously affect infant growth in the first few months of life. For example, breastfeeding appears to protect against obesity later in childhood, yet breastfed infants usually exhibit higher body mass during the first year of life than formula-fed infants. Although it is likely that accelerated growth confers an additional risk to the growth-retarded fetus, these conflicting results demonstrate the need for additional, carefully designed studies to determine just how childhood growth rates affect the later development of cardiovascular disease and type 2 diabetes.

Size at Birth, Insulin Secretion, and Insulin Action

The mechanisms underlying the association between size at birth and impaired glucose tolerance or type 2 diabetes are unclear. A number of studies in children and adults have shown that nondiabetic or prediabetic subjects with low birth weight are insulin resistant and thus are predisposed to development of type 2 diabetes (Phillips et al., 1994; Yajnik et al., 1995; Lithell et al., 1996; Clausen et al., 1997; Hoffman et al., 1997; Leger et al., 1997; McKeigue et al., 1998; Bavdekar et al., 1999; Flanagan et al., 2000; Li et al., 2001). IUGR is known to alter the fetal development of adipose tissue, which is closely linked to the development of insulin resistance (Widdowson et al., 1979; Lapillonne et al., 1997). In a well-designed case-control study of 25-year-old adults, Jaquet and colleagues (2000) demonstrated that individuals who were born SGA at 37 weeks or later had a significantly higher percentage of body fat (15%). Insulin sensitivity, even after adjustment for BMI or total fat mass, was markedly impaired in these SGA subjects. There were no significant differences between the SGA and control groups with respect to parental history of type 2 diabetes, cardiovascular disease, hypertension, or dyslipidemia. Of importance to generalization of the findings to other populations, the causes of IUGR in these subjects were gestational hypertension (50%), smoking (30%), maternal short stature (7%), congenital anomalies (7%), and unknown (6%).

The adverse effect of IUGR on glucose homeostasis was originally thought to be mediated through programming of the fetal endocrine pancreas. Growth-restricted fetuses and newborns have been shown to have a reduced population of pancreatic β -cells (Van Assche et al., 1977). Jensen and colleagues (2002) measured insulin secretion and insulin sensitivity in a well-matched population of 19-year-old, glucose-tolerant white men whose birthweights were either below the 10th percentile (SGA) or between the 50th and 75th percentiles (controls). To eliminate the major confounding factors, such as “diabetes genes,” the researchers ensured that none of the participants had a family history of diabetes, hypertension, or ischemic heart disease. They found no differences between the groups with regard to current weight, BMI, body composition, and lipid profile. When data were controlled for insulin sensitivity, insulin secretion was found to be lower by 30%. However, insulin sensitivity was normal in the SGA subjects. These investigators hypothesized that defects in insulin secretion may precede defects in insulin action and that once SGA individuals accumulate body fat, they do demonstrate insulin resistance.

Epidemiologic Challenges

The data described in the preceding section suggest that low birth weight is associated with glucose intolerance, type 2 diabetes, and cardiovascular disease. However, the question remains whether these associations reflect fetal nutrition or other factors that contribute to birthweight and the observed glucose intolerance. Because of the retrospective nature of the cohort identification, many confounding variables were not always recorded, such as lifestyle, socioeconomic status, education, maternal age, parental build, birth order, obstetric complications, smoking, and maternal health. Maternal nutritional status, either directly in the form of diet histories or indirectly in the form of BMI, height, and pregnancy weight gain, were usually not recorded. Instead, birth anthropometric measures were used as proxies for presumed undernutrition in pregnancy.

Size at Birth Cannot Be Used as a Proxy for Fetal Growth

Birthweight is determined by the sum of multiple known and unknown factors, including GA, maternal age, birth order, genetics, maternal prepregnancy BMI, and pregnancy weight gain, plus multiple environmental factors, such as smoking, drug use, infection, and maternal hypertension. Some of these determinants may be related to susceptibility to adult disease, and others may not. Conversely, some prenatal determinants of adult outcomes may not be related to fetal growth. A good example of how size at birth may potentially be a proxy for an underlying causal pathway is the hypothesis that essential hypertension in the adult is due to a congenital nephron deficit (Brenner et al., 1993). A study has now shown that kidney volume is smaller in adults who were thinner at birth, after adjustment for current body size.

Genetics versus Environment

Several epidemiologic and metabolic studies of twins and first-degree relatives of patients with type 2 diabetes have demonstrated an important genetic component of diabetes (Vaag et al., 1995). The association between low birth weight and risk of type 2 diabetes in some studies could theoretically be explained by a genetically determined reduced fetal growth rate. In other words, the genotype responsible for type 2 diabetes may itself restrict fetal growth. This possibility forms the basis for the *fetal insulin hypothesis*, which suggests that genetically determined insulin resistance could result in insulin-mediated low growth rate in utero as well as insulin resistance in childhood and adulthood (Hattersley and Tooke, 1999). Insulin is one of the major growth factors in fetal life, and monogenic disorders that affect the fetus's insulin secretion or insulin resistance also affect its growth (Elsas et al., 1985; Froguel et al., 1993; Stoffers et al., 1997; Hattersley et al., 1998). Mutations in the gene encoding glucokinase have been identified that result in low birth weight and maturity-onset diabetes of the young. Although such mutations are rare, and no analogous common allelic variation has yet been discovered, it is likely that some variations exist that, once identified, will explain a proportion of the cases of diabetes in LBW subjects.

There is obviously a close relationship between genes and the environment. Not only can maternal gene expression alter the fetal environment but also the maternal intrauterine environment affects fetal gene expression. An adverse intrauterine milieu is likely to have profound long-term effects on the developing organism that may not be reflected in birthweight.

Cellular Mechanisms of Developmental Programming

Fetal malnutrition has two main causes: poor maternal nutrition and placental insufficiency. In the extensive literature about the fetal origins hypothesis, these two concepts have not been clearly discerned. Such a distinction is necessary, however, because maternal nutrition has probably been adequate in the majority of populations in which the hypothesis has been tested. Only extreme maternal undernutrition, such as occurred in the Dutch famine, reduces the birthweight to an extent that could be expected to raise the risk of adult disease (Lumey et al., 1995). Thus it is reasonable that placental insufficiency has been a main cause of low birth weight in these populations. The oxygen and nutrients that support

fetal growth and development rely on the entire nutrient supply line, beginning with maternal consumption and body size but extending also to uterine perfusion, placental function, and fetal metabolism. Interruptions of the supply line at any point could result in programming of the fetus for the future risk of adult diseases.

The intrauterine environment influences development of the fetus by modifying gene expression in both pluripotent cells and terminally differentiated, poorly replicating cells. The long-range effects on the offspring (into adulthood) are determined by which cells are undergoing differentiation, proliferation, or functional maturation at the time of the disturbance in maternal fuel economy. The fetus also adapts to an inadequate supply of substrates (such as glucose, amino acids, fatty acids, and oxygen) through metabolic changes, redistribution of blood flow, and changes in the production of fetal and placental hormones that control growth.

The fetus's immediate metabolic response to placental insufficiency is catabolism, consuming its own substrates to provide energy. A more prolonged reduction in availability of substrates leads to a slowing in growth. This enhances the fetus's ability to survive by reducing the use of substrates and lowering the metabolic rate. Slowing of growth in late gestation leads to disproportion in organ size, because the organs and tissues that are growing rapidly at the time are affected the most. Placental insufficiency in late gestation may, for example, lead to reduced growth of the kidney, which is developing rapidly at that time. Reduced replication of kidney cells may permanently reduce cell numbers, because there seems to be no capacity for renal cell division to catch up after birth.

Substrate availability has profound effects on fetal hormones and on the hormonal and metabolic interactions between the fetus, placenta, and mother. These effects are most apparent in the fetus of the mother with diabetes. Higher maternal concentrations of glucose and amino acids stimulate the fetal pancreas to secrete exaggerated amounts of insulin and the fetal liver to produce higher levels of insulin-like growth factors. Fetal hyperinsulinism stimulates the growth of adipose tissue and of other insulin-responsive tissues in the fetus, often leading to macrosomia. However, many offspring of diabetic mothers with fetal hyperinsulinism are not overgrown by usual standards, and many with later obesity and glucose intolerance were not macrosomic at birth (Pettitt et al., 1987; Silverman et al., 1995). These observations suggest that birthweight is not a good indication of intrauterine nutrition.

Molecular Mechanisms of Developmental Programming: Epigenetics

Epigenetics is the study of heritable changes in gene expression or phenotype occurring without changes in DNA sequence and is critically important for embryogenesis and normal fetal development. The best example of how epigenetic mechanisms can influence fetal growth are imprinting disorders such as Angelman syndrome and Beckwith–Wiedemann syndrome. Epigenetic modifications of the genome provide a mechanism that allows the stable propagation of gene activity states from one generation of cells to the next. There are at least two distinct classes of epigenetic information that can be inherited with chromosomes. One class of epigenetic control of gene expression involves changes in chromatin proteins, usually involving modifications of histone tails. In eukaryotes, DNA is assembled with histones to form the nucleosome, in which

DNA is wrapped approximately two turns around an octameric complex composed of two molecules of each of the four histones H2A, H2B, H3, and H4. The amino termini of histones can be modified by acetylation, methylation, sumoylation, phosphorylation, glycosylation, and ADP ribosylation.

The second class of epigenetic regulation is DNA methylation, in which a cytosine base is modified by a DNA methyltransferase at the C5 position of cytosine, a reaction that is carried out by various members of a single family of enzymes. Approximately 70% of CpG dinucleotides in human DNA are constitutively methylated, whereas most of the unmethylated CpGs are located in CpG islands. CpG islands are CG-rich sequences located near coding sequences and serve as promoters for the associated genes. Approximately half of mammalian genes have CpG islands. DNA methylation is commonly associated with gene silencing and contributes to X-chromosomal inactivation, genomic imprinting, as well as transcriptional regulation of tissue-specific genes during cellular differentiation (Gopalakrishnan et al., 2008). The methylation status of CpG islands within promoter sequences works as an essential regulatory element by modifying the binding affinity of transcription factors to DNA binding sites.

Most CpG islands remain unmethylated in normal cells; however, under some circumstances such as cancer (Klutstein et al., 2016) and oxidative stress, they can become methylated *de novo*. It is not known why particular CpGs are susceptible to aberrant methylation. A study by Feltus et al. (2003) suggests that there is a “sequence signature associated with aberrant methylation.”

The metabolic or nutritional state of the organism directly influences epigenetic modifications, as essentially all known epigenetic modifications rely upon substrates derived from intermediary metabolism such as S-adenosyl methionine, acetyl CoA, α -ketoglutarate, and nicotinamide adenine dinucleotide (Kaelin and McKnight, 2013).

There are numerous studies in humans examining the relationship between decreased fetal nutrient availability and epigenetic modifications in the offspring (Rakyan et al., 2011). Many of these are confounded by small sample size, cellular heterogeneity of tissues examined, and lack of validation. Moreover, most DNA methylation assays are performed in total peripheral blood monocytes, where the unique methylation profiles of the various cellular lineages complicate interpretation of the data. Furthermore, most changes appear to be stochastic and not reproducible in other cohorts. Despite these issues, multiple studies in diverse populations repeatedly show changes in DNA methylation associated with low birth weight or altered nutrient availability. Thus it is likely that an adverse *in utero* milieu does indeed induce epigenetic modifications in the offspring, but whether these modifications have biologic relevance remains to be determined. The field of “epigenetic epidemiology” remains an active and growing field of investigation.

Macrosomia

Excessive fetal growth (macrosomia, being LGA) is found in 9%–13% of all deliveries and can lead to significant complications in the perinatal period (Gregory et al., 1998; Wollschlaeger et al., 1999). Maternal factors associated with macrosomia during pregnancy include increasing parity, higher maternal age, and maternal height. Additionally, the previous delivery of a macrosomic infant, prolonged pregnancy, maternal glucose intolerance, high prepregnancy weight or obesity, and large pregnancy weight gain have all been found to raise the risk of delivering a macrosomic

infant (Mocanu et al., 2000; Weissmann-Brenner et al., 2012; Rossi et al., 2013).

Maternal complications of macrosomia include morbidities related to labor and delivery, such as prolonged labor, arrest of labor, and higher rates of cesarean section and instrumentation during labor. Also, the risks of maternal lacerations and trauma, delayed placental detachment, and postpartum hemorrhage are higher for the woman delivering a macrosomic infant (Lipscomb et al., 1995; Perlow et al., 1996). Complications of labor are more pronounced in primiparous women than in multiparous women (Mocanu et al., 2000). The neonatal complications of macrosomia include traumatic events such as shoulder dystocia, brachial nerve palsy, birth trauma, and associated perinatal asphyxia. Other complications for the neonate are elevated insulin levels and metabolic derangements, such as hypoglycemia and hypocalcemia (Wollschlaeger et al., 1999). In a large population-based study in the United States, macrosomia (defined as birthweight greater than 4000 g) was detected in 13% of births. Of these, shoulder dystocia was noted in 11% (Gregory et al., 1998).

Macrosomia is often not detected during pregnancy and labor. The clinical estimation of fetal size is difficult and has significant false-positive and false-negative rates. Ultrasonography estimates of fetal weight are not always accurate, and the literature reports a wide range of sensitivity estimates for the ultrasound detection of macrosomia. Additionally, there is controversy in how to define macrosomia and which ultrasound measurement is most sensitive in its prediction. Smith and colleagues (1997) have demonstrated a linear relation between AC and birthweight. They showed that the equations commonly used for estimated fetal weight have a median error rate of 7%, with greater errors seen with larger infants. Using receiver operating characteristic curves to measure the diagnostic accuracy of ultrasound, O'Reilly-Green and Divon (1997) reported sensitivity and specificity rates of 85% and 72%, respectively, for estimation of birthweight exceeding 4000 g. In their study, the positive predictive value (i.e., a positive test result

represents a truly macrosomic infant) is about 49%. Chauhan and associates (2000) found lower sensitivity for the use of ultrasound measurement of AC, HC, and FL (72% sensitivity), similar to the sensitivity of using clinical measurements alone (73%). Other investigators have shown that clinical estimation of fetal weight (43% sensitivity) had higher sensitivity and specificity than ultrasound evaluation in predicting macrosomia (Gonen et al., 1996). In a retrospective study, Jazayeri and coworkers (1999) showed that an ultrasound measurement of AC of greater than 35 cm predicts macrosomia in 93% of cases and is superior to measurements of BD or FL. Other researchers have reported that an AC of either more than 37 cm or more than 38 cm is a better predictor (Gilby et al., 2000; Al-Inany et al., 2001).

Numerous investigators have also questioned whether antenatal diagnosis improves birth outcomes in macrosomic infants. Investigators point to the low rates of specificity of antenatal tests resulting in high rates of false-positive results (O'Reilly-Green and Divon, 1997; Bryant et al., 1998). Antenatal identification of macrosomia (or possible macrosomia) may lead to a higher rate of cesarean section performed for infants with normal birthweights (Gonen et al., 2000; Mocanu et al., 2000; Parry et al., 2000). Macrosomia is a risk factor for shoulder dystocia, but the majority of cases of shoulder dystocia and birth trauma occur in nonmacrosomic infants (Gonen et al., 1996). A retrospective study of infants weighing more than 4200 g at birth showed a cesarean section rate of 52% in infants predicted antenatally to have macrosomia, compared with 30% in infants without such an antenatal prediction. The antenatal prediction of fetal macrosomia is also associated with a higher incidence of failed induction of labor and no reduction in the rate of shoulder dystocia (Zamorski and Biggs, 2001). Using retrospective data from a 12-year period, Bryant and colleagues (1998) estimated that a policy of routine cesarean section for all infants with estimated fetal weight greater than 4500 g would require between 155 and 588 cesarean sections to prevent a single case of permanent brachial nerve palsy.

Summary

There are many identified biologic and genetic factors associated with normal and abnormal fetal growth. Physicians are limited in their ability to identify a causative agent in every case. Modification of fetal growth is possible and occurs from such diverse influences as socioeconomic status, maternal nutrition, and maternal constitutional factors. Abnormal fetal growth influences

not only acute perinatal outcomes but also health during infancy, childhood, and, intriguingly, adulthood. In schools of public health, students are taught to search “up river” for solutions to health problems. Solutions for ill health in adulthood may lie in the identification of methods to improve the health of the fetus.

Multiple Gestations and Assisted Reproductive Technology

DARCY E. BROUGHTON AND EMILY S. JUNGHEIM

KEY POINTS

- The multiple birth rate has increased by 76% in the past three decades.
- Increased utilization of assisted reproductive technologies and women delaying childbearing are the main contributors to the increase in multiples.
- Multiple gestations are at high risk for both maternal and fetal morbidity and mortality, which increase as fetal number increases.
- Zygosity and chorionicity are important predictors of perinatal morbidity, with monochorionic diamniotic and monochorionic monoamniotic twins at higher risk.
- The risk of monozygotic twinning is increased in in vitro fertilization (IVF); etiologies may include zona manipulation and extended in vitro culture.
- Most neonatal complications in multiple gestations are sequelae of prematurity, including low birthweight, respiratory distress syndrome, neonatal intensive care unit (NICU) admission, intraventricular hemorrhage, and necrotizing enterocolitis.
- Up to 80% of women with multiple gestations experience antepartum complications, which include preterm labor, preterm premature rupture of membranes (PPROM), and placental abruption.
- Women carrying multiples are at increased risk for the three major causes of maternal mortality: postpartum hemorrhage, venous thromboembolism, and hypertensive disorders.
- Multiple gestations are associated with increased financial and psychosocial costs.
- Strategies for decreasing the rate of multiples resulting from assisted reproductive technology (ART) include increasing the number of single embryo transfers performed in IVF and using “low and slow” protocols for superovulation cycles with gonadotropins.
- Multifetal pregnancy reduction can be performed to decrease the fetal number and lower the risk of morbidity, although the procedure does involve some medical and psychological risk.

Epidemiology of Multiples

There are multiple factors influencing the increase in multiple births in the United States in the past half-century. The incidence of multiples was stable through the 1970s at 2% of all births ([Martin et al., 2012](#)). We then began to see an “epidemic of multiples,” with the twin birth rate increasing by 76% from 1980 to 2009 ([Martin et al., 2012](#)). The overall proportion of total

national births that were multiples increased from 1.8% in 1971 to 3.5% in 2011 ([Kulkarni et al., 2013](#)). Twins continue to account for the vast majority of multiple pregnancies, comprising 96% in 2009 ([Martin et al., 2012](#)). The growing use of assisted reproductive technology (ART), in addition to delayed childbearing until age-related fertility issues become apparent, has contributed greatly to multiple birth rates. The rate of women delaying childbearing has dramatically increased, with women over the age of 30 accounting for 20% of births in 1980, compared with more than 35% in 2009 ([Martin et al., 2012](#)). Between 1980 and 2009, the twin birth rate increased by 100% in women 30–35 years old and by more than 200% in women aged 40 and older ([Martin et al., 2012](#)). In 2009, 7% of all births to women aged 40 or older were twins ([Martin et al., 2012](#)). Spontaneous twinning is more common as women age, perhaps related to higher follicle-stimulating hormone (FSH) levels in the follicular phase leading to ovulation of more than one oocyte, with a peak at age 37 ([Hall, 2003](#)). However, the increasing age of childbearing women is estimated to account for only one-third of the rise in twinning, with ART responsible for the remainder ([Martin et al., 2012](#)). Since the birth of the first in vitro fertilization (IVF) baby in 1978, the numbers of IVF clinics, ovarian stimulation cycles, and live births from ART have all steadily increased. In 2013, ART contributed to the births of 1.6% of total infants, 18.7% of multiple birth infants, and 25.2% of triplet and higher order multiple (HOM, 4 or more) infants ([Sunderam et al., 2015](#)). About 3.5% of all US births are multiples, yet in 2013 the ART twin birth rate was 39% and the ART HOM birth rate was 2% ([Sunderam et al., 2015](#)).

It is important to note that, since 1997, IVF has *not* been the leading contributor to the multiple birth rate, contributing to only 16% of multiple births in 2013 ([Adashi, 2016](#)). Non-IVF treatment options including ovulation induction with oral medications and superovulation with injectable gonadotropins were responsible for 19% of twins and 45% of triplet or HOMs in 2011 ([Kulkarni et al., 2013](#)). These modalities involve less monitoring and are subject to less control than IVF and are thus less susceptible to efforts to decrease the multiples rate. While the twin birth rate has continued to increase, the proportion of triplet or HOM births arising from medically assisted conceptions has been declining in recent years, from 84% in 1998 to 77% in 2011 ([Kulkarni et al., 2013](#)). The incidence of triplet and HOM births increased by a factor of 6.7 from 1971 to 1998 but has since decreased by 29% from 1998 to present ([Kulkarni et al., 2013](#)). This is largely due

to a decrease in the number of embryos transferred per cycle of IVF and to the reticence of providers to use superovulation with injectable gonadotropins.

Given the maternal, perinatal, and neonatal complications associated with multiples, the goal of infertility treatment is one healthy child. Multifetal pregnancies drastically affect individuals, families, and public health systems. Of particular importance in both maternal and fetal outcomes are fetal number and placentation.

Diagnosing Zygosity and Chorionicity

Determining zygosity and chorionicity is important medically, genetically, and psychosocially for the individual and family. More immediately, the chorion–amnion arrangement is crucial to antepartum management, as it determines risks of complications such as twin–twin transfusion syndrome (TTTS), growth discordance, intrauterine growth restriction (IUGR), congenital anomalies, and cord accidents. Chorionicity also guides next steps in cases of one fetal demise or desired selective reduction. Zygosity refers to the number of oocytes and spermatozoa involved in conception. Dizygotic twins result from fertilization of two separate ova by two spermatozoa, and these comprise 67% of spontaneous twins (Gibbs and Danforth, 2008). Monozygotic twins (MZTs) are identical and result from fertilization of a single ovum with one spermatozoa and subsequent postzygotic division (McNamara et al., 2016). The timing of this division, or splitting, determines the number of fetuses, chorionic plates, and amniotic sacs.

To determine zygosity we can use prenatal determination of fetal gender or blood typing and DNA analysis in the postnatal period (Hall, 2003; Ohm et al., 2006). Diagnosing chorionicity is possible using ultrasound markers including the number of placental sites, thickness of dividing membrane, and the lambda sign. The lambda sign indicates dichorionicity and is a triangular projection of tissue that extends beyond the chorionic surface of the placenta (Finberg, 1992).

A first trimester screening ultrasound is essential in diagnosing multiple pregnancy. In a large randomized trial, in the cohort of women that did not have a screening ultrasound, 37% were not diagnosed as having a twin pregnancy until 26 weeks, and 13% were not diagnosed until the time of delivery (LeFevre et al., 1993). Current ultrasonographic technology is very effective at diagnosing chorionicity and amnionicity. In one study, the reported sensitivity, specificity, and positive and negative predictive values for ultrasonography at less than 14 weeks' gestation were 89.8%, 99.5%, 97.8%, and 97.5%, respectively. Overall, chorionicity was correctly diagnosed in 95% of cases (Lee et al., 2006) (Table 7.1).

The Effect of Chorionicity

Chorionicity and placentation greatly affect fetal morbidity and mortality in multifetal pregnancies. Dizygotic twins (DZTs), with few exceptions, lead to a dichorionic diamniotic (DCDA) arrangement in which the placenta can be separate or fused. Rare cases of dizygotic monochorionic diamniotic (MCDA) twins have been reported (Souter et al., 2003). Theories as to the etiology of this include fusion of two genetically distinct zygotes or fertilization of a binovular follicle (McNamara et al., 2016). The highest rates of spontaneous twinning are in Nigeria, where 1 out of every 12 persons is a member of a twin pair, and the lowest twinning rates are seen in China, where 1 in every 70 persons is a member of a twin pair. North American and European countries are considered

TABLE 7.1

Twinning Rates per 1000 Births by Zygosity

| Country | Monozygotic | Dizygotic | Total |
|-------------------|-------------|-----------|-------|
| Nigeria | 5.0 | 49 | 54 |
| United States | | | |
| African American | 4.7 | 11.1 | 15.8 |
| Caucasian | 4.2 | 7.1 | 11.3 |

From MacGillivray I. Epidemiology of twin pregnancy. *Semin Perinatol.* 1986;10:4–8; and Cunningham FG, Hauth JC, Wenstrom KD, et al. (eds). *Williams Obstetrics*, ed. 22, New York: McGraw-Hill; 2005.

to have an intermediate prevalence of spontaneous dizygotic twinning (Hoekstra et al., 2008). Risk factors for DZT include advancing maternal age, increased parity, female relatives with DZT, taller height, and higher body mass index (MacGillivray, 1986; Hoekstra et al., 2008). Historically, a seasonal trend in DZT has been seen, with higher rates in the summer and autumn months (Hoekstra et al., 2008).

The true incidence of MZTs is difficult to ascertain because of its rarity, inaccuracies in diagnosis, and lack of confirmatory studies at birth, but spontaneous MZT rates are estimated to occur in 0.3%–0.5% of all pregnancies and in less than 30% of all twins (Bulmer, 1970; MacGillivray, 1986; Hall, 2003). This rate was geographically constant prior to the advent of ART (Hall, 2003). Unlike DZT, it is unclear whether MZT is related to genetics or environment (Bortolus et al., 1999; Hoekstra et al., 2008). Familial association has been seen but is very rare (Hall, 2003; Hamamy et al., 2004).

Chorionicity in monozygotic gestations is determined by the timing of the embryonic division (Figs. 7.1 and 7.2). In 18%–36% of MZTs, the zygote divides within 72 hours of fertilization, resulting in a DCDA gestation (the placenta can be separate or fused); 60%–75% split between days 4 and 8, leading to a MCDA unit; and 1%–2% separate between days 8 and 13, leading to an monochorionic monoamniotic (MCMA) pregnancy. Embryonic division after day 13 results in conjoined twins that are MCMA (Hall, 2003; Gibbs and Danforth, 2008; Cunningham and Williams, 2010; McNamara et al., 2016).

There are no naturally occurring animal models of MZT with the exception of armadillos. Models of MZT can be induced in laboratory animals by exposure to toxins, hypoxia, or manipulation of the zona pellucida (Hall, 2003; Knopman et al., 2014). The cause of spontaneous monozygotic twinning in humans is unknown. An uneven sex ratio has been noted, with 0.484 male:female pairs in all monozygotic twins and 0.231 in monoamniotic twins (Derom et al., 1988; Hall, 2003), leading to the theory that skewed X inactivation may play a role. The development of two inner cell masses (ICM) at the blastocyst stage can lead to MZT, either from damage or through immune-mediated cell-to-cell crosstalk (Hall, 2003).

Although the majority of ART MZTs are MCDA, any of the three monozygotic placental arrangements can transpire after ART, implying that the timing and mechanism of embryonic splitting

| Zygosity | Dizygotic or Monozygotic | | Monozygotic | |

are variable (Aston et al., 2008; Knopman et al., 2010). To date, embryonic splitting has not been observed in vitro (Vithala et al., 2009).

Increase in Monozygotic Twins With Assisted Reproductive Technology

The first reported association between ART and MZT (Yovich et al., 1984) preceded numerous accounts of similar findings. The

majority (>90%) of ART twins are dizygotic (Gibbs et al., 2008) secondary to transferring multiple embryos; however, the rate of MZTs per pregnancy after fertility treatment is higher (0.7%–13%) (Sills et al., 2000; Schachter et al., 2001; Alikani et al., 2003; Aston et al., 2008; Vithala et al., 2009; Knopman et al., 2010) versus the general population (0.3%–0.5%) (Bulmer, 1970; MacGillivray, 1986). It is also suspected that the incidence of MZT in ART may be underestimated because DCDA gestations after transfer of more than one embryo are often assumed to be dizygotic, and genetic analysis is rarely performed postnatally

(Knopman et al., 2014). Several theories to explain the mechanism responsible for elevated MZTs with ART have been proposed. Following is a discussion of those theories.

Age

As mentioned previously, spontaneous dizygotic twinning increases with advancing maternal age (Bulmer, 1970; Bortolus et al., 1999; MacGillivray, 1986), but the connection between age and MZTs is controversial. Some studies report trends toward elevated MZT rates in older women (Bulmer, 1970; Abusheikha et al., 2000; Alikani et al., 2003), whereas others found no association with increasing maternal age and MZT (Bortolus et al., 1999; Skiadas et al., 2008), and one study found that the MZT risk doubles in women younger than 35 years (Knopman et al., 2010). Overall, the correlation between age and MZT in ART remains unclear.

Zona Pellucida Manipulation

The zona pellucida (ZP), an acellular protein surrounding the ovum, provides a species-specific sperm barrier and decreases polyploidy by inhibiting penetration by multiple sperm (Fritz and Speroff, 2011). It has been shown that the thickness and hardness of the ZP can vary in relation to stimulation protocol, elevated FSH or estradiol (E2) levels, and culture conditions. There is debate as to whether ZP manipulations performed during IVF affect MZT risk. Manipulation of the ZP in IVF occurs via both intracytoplasmic sperm injection (ICSI) and assisted hatching (AH). The injection of one sperm into a mature oocyte (i.e., ICSI) is most commonly performed for male factor infertility. AH is achieved with an artificial breach in the ZP by laser, chemical, or mechanical methods and has been shown to increase clinical pregnancy rates, although not live birth rates, in patients with a poor prognosis (Practice Committee of the American Society for Reproductive Medicine; Practice Committee of the Society for Assisted Reproductive Technology, 2014). A recent Cochrane Review demonstrated that AH is associated with an increase in multiple pregnancy, with an odds ratio of 1.39 (Carney et al., 2012). However, the increase in MZT with AH was not statistically significant, and this was confirmed in other large studies (Sills et al., 2000; Valojerdi et al., 2008; Knopman et al., 2010; Carney et al., 2012). However, the data are conflicting, with a retrospective review of over 35,000 IVF cycles showing a threefold risk of MZT with AH (Schieve et al., 2000), a finding also demonstrated in many smaller studies (Alikani et al., 2003; Skiadas et al., 2008). Similarly, there are mixed data to support that ICSI increases the risk of MZT. The most recent committee opinion from the American Society for Reproductive Medicine endorses that the data confirm an association (Abusheikha et al., 2000; Vitthala et al., 2009; Practice Committee of the American Society for Reproductive Medicine, 2012). However, more recent data have called this into question, with a recent study examining twinning after single embryo transfer finding a decrease in rates of MZT with ICSI (Kanter et al., 2015). Interestingly, the defect created in the ZP for ICSI is much smaller than for AH, lending plausibility to other recent studies that have shown no association (Nakasuji et al., 2014; Sobek et al., 2015; Vaughan et al., 2016).

Blastocyst Transfer

After oocyte retrieval and insemination, embryos undergo intra-uterine transfer at either the cleavage stage (day 2–3 after retrieval)

or the blastocyst stage (day 5–6 after retrieval). Blastocyst-stage embryo transfer yields higher live birth rates and lowers overall multiple rates because of an increase in single embryo transfer at the blastocyst stage (Frattarelli et al., 2003; Glujovsky et al., 2012). However, evidence has supported the increased incidence of MZTs with extended culture to the blastocyst stage (Behr et al., 2000; Milki et al., 2003; Toledo, 2005; Skiadas et al., 2008; Knopman et al., 2010; Sharara and Abdo, 2010; Kanter et al., 2015). The theory is that extended culture may impact the integrity of the ZP, causing herniation and splitting of the blastomeres (Alikani et al., 1994; Carrillo-Vadillo et al., 2007). One institution initially noted increased MZT after blastocyst transfer (5.6% vs 2%; Milki et al., 2003), but a follow-up study 3 years later demonstrated similar MZT rates between blastocyst and day 3 embryos (2.3% vs 1.8%), indicating that changes in culture media and an experienced embryology team may affect the rate of MZTs (Moayeri et al., 2007). Another recent study from a large IVF center showed a higher MZT rate with blastocyst transfer, but this association disappeared after controlling for patient age, embryo quality, and availability of supernumerary embryos (Franasiak et al., 2015). Higher-quality embryos are more likely to be cultured out to the blastocyst stage, which may be a confounder when comparing day of transfer. Recent data from this study and others also indicate that younger oocyte age, another marker of embryo quality, is related to higher incidence of MZT (Knopman et al., 2010, 2014; Franasiak et al., 2015). The role that culture media may play remains to be determined. Elevated glucose levels in extended culture and subsequent glucose-induced apoptotic remodeling of the ICM and ICM splitting in extended culture in murine and human embryos may explain the phenomenon of MZTs in blastocysts (Menezo and Sakkas 2002; Cassuto et al., 2003). Another environmental factor that may affect MZTs is temperature variation in frozen–thawed embryo cycles. Although minute evidence links frozen embryo transfers and temperature fluctuations to MZTs (Toledo, 2005; Faraj et al., 2008), most studies show no difference between fresh and frozen–thawed embryos and multiple rates or MZT rates (Alikani et al., 2003; Knopman et al., 2010).

Ovulation Induction and Superovulation

Human studies of ovarian stimulation with clomiphene citrate and gonadotropins reveal a twofold increased risk of MZTs compared with the general population. MZT incidences of 1.5% after ovulation induction with gonadotropins, 0.72% after IVF, and 0.87% with IVF with ICSI and AH suggest that elevated levels of steroid hormones may elevate MZTs regardless of ZP manipulation (Schachter et al., 2001). However, this finding may be confounded by a higher baseline risk of MZT in patients with infertility (Zhu et al., 2007).

Fetal Complications Associated With Multiples

Multiple pregnancies account for a small percentage of overall live births but are responsible for a disproportionate amount of morbidity and mortality. This is largely attributable to complications of prematurity, as women with multiple pregnancies are six times more likely to deliver preterm and 13 times more likely to deliver before 32 weeks than those with a singleton. Of multiple pregnancies, 11% are delivered before 32 weeks and 59% before 37 weeks, compared with 9.6% of singletons delivered preterm (Hamilton

TABLE 7.2 Morbidity and Mortality by Fetal Number

| Characteristic | Twins | Triplets | Quadruplets |
|--|--------------------------------|---------------------------------|-------------|
| Average birthweight | 2347 g | 1687 g | 1309 g |

NICU, Neonatal intensive care unit.

From American College of Obstetricians and Gynecologists Committee on Practice Bulletins—Obstetrics; Society for Maternal-Fetal Medicine; ACOG Joint Editorial Committee. ACOG Practice Bulletin #56: Multiple gestation: complicated twin, triplet, and high-order multifetal pregnancy. *Obstet Gynecol.* 2004;104:869–883.

et al., 2015). As a consequence, multiples have a fivefold increased risk of stillbirth and a sevenfold increased risk of neonatal death (Scher et al., 2002). The risk of prematurity increases with fetal number, with 9 out of every 10 triplets being born preterm or low birthweight (Hamilton et al., 2015). The average gestational ages at delivery for twins, triplets, and quadruplets are 35.3, 31.9, and 29.5 weeks, respectively (American College of Obstetricians and Gynecologists; Society for Maternal-Fetal Medicine, 2014), corresponding to neonatal intensive care unit (NICU) admission rates fivefold higher in twins and 17-fold higher in triplets and HOMs (Ross et al., 1999).

Fetal and maternal complications are more common in twin pregnancies, and this risk increases with triplets and HOMs (Table 7.2). Multiples have increased risks of intraventricular hemorrhage, periventricular leukomalacia, cerebral palsy, sepsis, necrotizing enterocolitis, and respiratory distress syndrome (Blondel and Kaminski, 2002; Rettwitz-Volk et al., 2003; Salihu et al., 2003; Luke and Brown, 2008). Surviving infants of preterm multifetal pregnancies have higher rates of developmental handicap (Yokoyama, et al., 1995; Rettwitz-Volk et al., 2003; Luke et al., 2006). Higher fetal number correlates with increased risk of growth restriction, earlier delivery, low birth weight (LBW), NICU admission, length of stay, risk of major handicap and cerebral palsy, and death in first year of life (Garite et al., 2004; Luke and Brown, 2008). A review of 100 triplet gestations (88 with assisted conception) revealed

that 78% experienced preterm labor (PTL), 14% delivered before 28 weeks, 5% had congenital anomalies, and 9.7% died in the perinatal period (Devine et al., 2001).

It is important to note that singleton pregnancies after assisted conception have increased complications, including preterm delivery, LBW, prolonged hospital stay, cesarean deliveries, blood transfusion, NICU admission, and mortality compared with spontaneous singletons (Helmerhorst et al., 2004; Jackson et al., 2004; Van Voorhis, 2006; Schieve et al., 2007; Martin et al., 2016). A common phenomenon in ART is the “vanishing twin,” an arrest of development and subsequent absorption of one or more fetuses of a multiple gestation in the first trimester (Practice Committee of the American Society for Reproductive Medicine, 2012). Estimates of the incidence of a vanishing twin after ART range from 10%–30% and are increased in HOMs (Landy and Keith 1998; Tummers et al., 2003; McNamara et al., 2016). Recent evidence suggests that the surviving twin(s) is at increased risk for LBW, preterm birth, and possibly cerebral impairment (Pinborg et al., 2005, 2007; Anand et al., 2007a, 2007b; Luke et al., 2009). The risk of LBW is related to the gestational age at the time of a twin demise, with later gestations conferring more risk (Pinborg et al., 2007). The majority of vanishing twins (80%) occur prior to 9 weeks (McNamara et al., 2016). Demise of a twin after the first trimester is more common in monozygotic gestations (Burke, 1990).

Similar to ART singleton versus spontaneous singleton outcomes, ART multiples may have higher morbidity compared with spontaneous multiples. Assisted-conception twins are at increased risk for LBW, preterm delivery, cesarean delivery, NICU admission, longer length of stay, respiratory distress syndrome, and birthweight discordance versus spontaneously conceived twins (Moise et al., 1998; Nassar et al., 2003; Smithers et al., 2003; Helmerhorst et al., 2004; McDonald et al., 2005). In contrast, other studies suggest comparable outcomes in assisted conception and spontaneous multiples. Rates of pregnancy-induced hypertension, gestational diabetes mellitus, preterm premature rupture of membranes (PPROM), placenta previa, placental abruption, congenital malformations, and mortality were similar in IVF twins versus spontaneous twins (Nassar et al., 2003; Pinborg et al., 2004; McDonald et al., 2005).

Besides fetal number, another critical factor in pregnancy outcome is placental architecture. Monochorionic multiples experience higher rates of morbidity and mortality, largely because of placental factors (Table 7.3) (Hack et al., 2008; Cunningham and Williams, 2010; Glinianaia et al., 2011). Negative outcomes such as stillbirth, neonatal mortality, congenital malformations, and cerebral palsy are higher in monochorionic twins compared with dichorionic twins (Lewi et al., 2010; Glinianaia et al., 2011; Burgess et al., 2014). These complications are thought to be related to placental sharing and the vascular anastomoses that may cause unequal distribution of placental blood flow, causing TTTS. TTTS affects 10% of MCDA gestations and usually presents in the second trimester with oligohydramnios of the donor twin and polyhydramnios in the recipient twin (Society for Maternal-Fetal Medicine and Simpson, 2013; American College of Obstetricians and Gynecologists; Society for Maternal-Fetal Medicine, 2014).

The severity of TTTS ranges from stage I to stage V, and sequelae can include hydrops and fetal death. The incidence of progression from stage I to more severe disease is 15%; the survival rate in those that don't progress is 86% (Bebbington et al., 2010; Rossi and D'Addario, 2013). The prognosis for TTTS that is stage III or higher is bleak, with a loss rate of 70%–100% (Berghella and Kaufmann, 2001; Hack et al., 2008). Overall, TTTS accounts for

TABLE 7.3 Incidence of Twin Pregnancy Zygosity and Chorionicity With Corresponding Complications

| Type of Twinning | Incidence (%) | COMPLICATION (%) | | |
|----------------------------|---------------|------------------|-------------------------------|---------------------|
| | | IUGR | Delivery <37 Weeks' Gestation | Perinatal Mortality |

IUGR, Intrauterine growth restriction.

From Cunningham FG, Hauth JC, Wenstrom KD, et al. (eds). *Williams Obstetrics*, ed. 22, New York: McGraw-Hill; 2005. Originally from Manning FA. Fetal biophysical profile scoring. In *Fetal Medicine: Principles and Practices*, Norwalk, CT: Appleton & Lange, 1995.

half of perinatal deaths in MCDA twins (Lewi et al., 2008, 2013), and surviving infants are at risk for long-standing adverse neurologic outcomes (Cleary-Goldman and D'Alton, 2008).

MCMA twins are very rare, occurring in 1 in 10,000 pregnancies, but they suffer the highest risk of perinatal morbidity and mortality (American College of Obstetricians and Gynecologists; Society for Maternal-Fetal Medicine, 2014). Similar to MCDA twins, MCMA twins are susceptible to TTTS, growth discordance, IUGR, preterm delivery, and congenital anomalies, but they also face the unique complication of cord entanglement (Cordero et al., 2006). These factors historically account for perinatal mortality rates of up to 80% (American College of Obstetricians and Gynecologists; Society for Maternal-Fetal Medicine, 2014). However, lower morbidity and mortality rates (2%–25%) reported in recent articles may be attributed to increased prenatal diagnosis and fetal surveillance (Cordero et al., 2006; Baxi and Walsh 2010; Murata et al., 2013).

Maternal Complications

Approximately 80% of women pregnant with multiples experience antepartum complications versus 25% of those with singletons, and hospitalization for hypertensive disorders, PTL, PPROM, placental abruption, and hyperemesis gravidarum are elevated sixfold (American College of Obstetricians and Gynecologists; Society for Maternal-Fetal Medicine, 2014; Norwitz et al., 2005). The risk of severe maternal morbidity, including intensive care unit admission, uterine rupture, eclampsia, major obstetric hemorrhage, and peripartum hysterectomy, is elevated fourfold (Witteveen et al., 2016). Mothers with two or more fetuses are at increased risk for the three major causes of maternal mortality: postpartum hemorrhage, venous thromboembolism, and hypertensive disorders (Conde-Agudelo et al., 2000; Walker et al., 2004). Hypertensive disorders occur in 20% of multiples compared with 6.5% of singletons (Day et al., 2005).

Plurality correlates with maternal morbidity, with triplets and HOMs experiencing significantly increased maternal morbidity

compared to twins. They have higher rates of PPROM, postpartum hemorrhage, gestational diabetes, placental abruption, cesarean delivery, and hypertensive disorders (Wen et al., 2004; Luke and Brown, 2008). Results of a triplet cohort showed that 96% had maternal complications, 96% required antenatal hospitalization, one in four were diagnosed with preeclampsia, and 44% encountered postpartum complications (Devine et al., 2001).

Psychosocial Factors

As would be expected, psychosocial stressors increase with pregnancy and delivery of multiples. As fetal number increases, parents report decreased quality of life, increased social stigma, increased financial stress, and decreased marital satisfaction (Glazebrook et al., 2004; Ellison et al., 2005; Golombok et al., 2007; Sheard et al., 2007; Roca de Bes et al., 2009; van den Akker et al., 2016). Studies have also demonstrated an increased risk of postpartum depression in mothers of multiples (Choi et al., 2009; Vilska et al., 2009; Ross et al., 2011). It is estimated that adequately caring for 6-month-old triplets and performing household duties would require 197.5 hours per week, clearly exceeding the 168 hours available (Bryan, 2003). Additionally, many multiple pregnancy infants are born preterm and have ongoing health issues, further exacerbating parental stress. Most studies have not demonstrated a psychosocial difference between naturally conceived multiples and multiples conceived with ART (Sydsjo et al., 2008; Vilska et al., 2009; Roca-de Bes et al., 2011; van den Akker et al., 2016).

Cost

Multiple gestations have a large economic impact, both for individual families and society. As previously discussed, multiples have increased risks of preterm delivery and LBW, which are the major drivers of short-term and long-term costs (Cuevas et al., 2005). The average first-year medical costs for preterm infants are 10 times higher than for term infants (American College of Obstetricians and Gynecologists; Society for Maternal-Fetal Medicine, 2014). According to gestational age, the mean initial hospital charge for infants born between 26 and 28 weeks' gestation is approximately \$240,000 compared with approximately \$4800 for a term infant. By birthweight, infants weighing less than 1250 g cost approximately \$250,000 compared with infants weighing more than 2500 g, who cost \$5800 (Cuevas et al., 2005). Overall, the cost of a twin gestation is fourfold to fivefold that of a singleton, and this increases to 10–20-fold for triplets and HOMs (Collins, 2007; Lemos et al., 2013).

ART multiples and their associated comorbidities have a significant role in healthcare expenditures. The estimated financial cost of ART-associated preterm deliveries in the United States is \$1 billion annually (Bromer et al., 2011). Women with ART pregnancies have higher rates of antenatal hospitalization with longer length of stay than women who conceived naturally, contributing to increased costs (Martin et al., 2016). A recent Dutch study showed that multiples conceived with IVF were 3.3 times more costly than singletons conceived with IVF through 5 years of life (van Heesch et al., 2015). If iatrogenic multiples were singletons in future, the estimated cost savings would be \$6.3 billion in the first year of life (Allen et al., 2014). Data also indicate that ART-conceived infants, especially in the case of multiples, have higher risks of hospital admission in the first 1–2 years of life, incurring additional costs (Pinborg et al., 2004; Hansen et al., 2009).

Decreasing the Risk of Multiples

Primary forms of preventing multiples include canceling ovulation induction cycles in which multifollicular development occurs, or converting those cycles to IVF, and limiting the number of embryos transferred in IVF cycles. Embryo transfer policies vary significantly on the global stage, ranging from strict legislation to recommendations from professional societies that are not binding. In some countries single embryo transfer (SET) is mandatory with rare exceptions (European IVF-Monitoring Consortium; European Society of Human Reproduction and Embryology, [Kupka et al., 2016](#)). The American Society for Reproductive Medicine (ASRM) and the Society for Assisted Reproductive Technology established transfer guidelines in the United States, beginning in 1998, to assist in determining an appropriate number of embryos to transfer and help decrease the rate of multiples. Recommended limits are based on age, prognosis, and embryo stage and further differentiate between a favorable prognosis (first IVF cycle, good-quality embryos, number of embryos for potential cryopreservation, successful past IVF cycles) and less favorable prognosis.

In the most recent 2013 guidelines, ASRM highly recommends consideration of SET in patients younger than 35 with a favorable prognosis ([Practice Committee of the American Society for Reproductive Medicine; Practice Committee of the Society for Assisted Reproductive Technology, 2013](#)). Recommendations state that the number of embryos transferred in a frozen cycle should not exceed the recommended limits in a fresh cycle. These transfer guidelines are not legally binding, and they are subject to interpretation or adjustment based on clinical experience and unique patient characteristics ([Practice Committee of the American Society for Reproductive Medicine; Practice Committee of the Society for Assisted Reproductive Technology, 2013](#)).

The rates of SET in the United States have been increasing in response to the epidemic of multiples, with the proportion of cycles in which one embryo was transferred increasing from 6% in 1971 to 21% in 2011. Similarly, the proportion in which three or more embryos were transferred decreased from 79% to 24% in that same time period ([Kulkarni et al., 2013](#)). The term “elective SET” (eSET) refers to couples who have more than one quality embryo available for transfer but elect to transfer one. The rate of eSET in the United States has historically been quite low but increased from 3.3% in 2008 to 9% in 2011 ([Practice Committee of the American Society for Reproductive Medicine, 2012; Kulkarni et al., 2013](#)). These efforts have resulted in an increase in the singleton birth rate after IVF, which increased by 29% from 1998 to 2011, with 2005 marking the first year that more than half of IVF deliveries were singletons ([Kulkarni et al., 2013](#)).

There are many factors contributing to the increase in SET and stabilization of the multiple birth rate. These include revised guidelines from ASRM that lowered the recommended number of embryos to transfer, improved technology leading to more blastocyst transfers, and expanded insurance coverage for ART ([Kulkarni et al., 2013](#)). The overall number of embryos transferred each year has steadily declined since publication of the initial ASRM guidelines in 1998, and it is estimated that between 13,500 and 16,300 HOM deliveries have been prevented, which is a cost savings of more than \$6 billion ([Stern et al., 2007; Lee et al., 2016](#)).

A recent metaanalysis compared the effectiveness of eSET to double embryo transfer (DET). Overall live birth rates (LBR) were lower after SET (27%) than DET (42%), but the cumulative LBR after one additional frozen single embryo transfer was not

significantly different. The likelihood of a singleton LBR was five times higher in the SET group ([Thurin et al., 2004; McLernon et al., 2010](#)). Birth rates with SET and DET seem to be more comparable with blastocyst transfers than with cleavage stage transfers. One program in the United States mandates SET in patients less than 38 years old with more than seven zygotes and at least one quality blastocyst. After implementation of this mandate in 2004, they demonstrated an overall increase in LBR (51.1% to 55.9%) and a decrease in the rate of multiples (34.8% to 17.5%). The LBR in the mandated single embryo transfer (mSET) group was impressive at 64.6% with only 3.4% multiples (monochorionic gestations) ([Kresowik et al., 2011](#)). A study comparing SET at the blastocyst versus the cleavage stage found significantly higher pregnancy rates in the blastocyst group, and this is reflected in the ASRM transfer guidelines ([Papanikolaou et al., 2006](#)).

Expanding insurance coverage for ART is another strategy that may help to decrease multiple births. Currently, 15 states have enacted infertility insurance mandates that vary in the ART services covered. Studies have shown that women with insurance coverage are more likely to elect for SET, likely with the goal of accelerating the process of family building and avoiding the cost of future cycles ([Griffin et al., 2012; Adashi, 2016; Styer et al., 2016](#)).

Patient education is a powerful tool to increase the acceptability of eSET. Many patients are undereducated as to the risks and complications associated with multiples and elect to have more than one embryo transferred because of a desire for twins. It is incumbent upon providers to explain the multitude of reasons that one healthy liveborn infant is the goal of every IVF cycle. Educational programs targeted to improve attitudes toward SET have shown some success ([Newton et al., 2007; Ryan et al., 2007; Hope and Rombauts, 2010; Griffin et al., 2012](#)).

Strategies for reducing multiples caused by non-IVF infertility therapy should also be considered. As previously discussed, ovulation induction and superovulation contribute up to 20% of twin births in the United States ([Adashi, 2016](#)). During superovulation cycles with gonadotropin stimulation, follicular growth is monitored with ultrasound, and E2 levels are serially measured in an attempt to minimize multifollicular development. Overall the risk of multiples correlates with increasing E2 levels and the size and number of follicles ([Dickey, 2009; Practice Committee of the American Society for Reproductive Medicine, 2012](#)). However, an attempt to define thresholds at which couples are at low risk for multiples has been unsuccessful ([Ragni et al., 1999; Gleicher et al., 2000; Ghesquiere et al., 2007; Rosen et al., 2008](#)). A strategy that has shown promise is the use of “low and slow” protocols, using low-dose gonadotropin stimulation over a longer period of time. Studies examining these protocols have documented multiple rates of 1.0% or less ([Papageorgiou et al., 2004; Ragni et al., 2006](#)). Lastly, some have advocated for the elimination of superovulation as an intermediary step between oral ovulation induction and IVF, given the associated high rate of multiples and HOMs, and this has been adopted as a cost-effective strategy by some health plans ([McClamrock et al., 2012; Adashi, 2016](#)).

Multifetal Pregnancy Reduction

As the rates of ART procedures, multiple pregnancies, and prematurity-related sequelae have increased, so has the use of selective reduction. Primary prevention of multiple gestations is optimal; however, in reality, multifetal pregnancies continue to occur. Multifetal pregnancy reduction (MFPR) provides an option to reduce the risk of fetal or neonatal morbidity and mortality

(Practice Committee of the American Society for Reproductive Medicine, 2012; American College of Obstetricians and Gynecologists; Society for Maternal-Fetal Medicine, 2014). First developed in the 1980s, termination of one or more fetuses is performed to reduce the final fetal number. The procedure most often involves passage of a needle transabdominally into the thorax of the fetus and subsequent injection of potassium chloride (Evans et al., 2014). Selective termination refers to reduction of an abnormal fetus that is part of a multifetal gestation. The majority of patients choose to reduce a triplet or HOM pregnancy to twins, but the number reducing to singletons is increasing with heightened awareness of the morbidity associated with twins (Stone et al., 2008; Evans et al., 2014). Improvements in MFPR techniques have enhanced

success rates such that quadruplet or triplets reduced to twins have comparable outcomes to natural twins (Evans et al., 2014). Studies have shown that reduction of triplet pregnancies to twins reduces the risk of preterm birth, LBW, cesarean delivery, and neonatal death (Dodd and Crowther, 2004). The average loss rate currently quoted as a complication of MFPR is about 4%, down from 13% in the 1990s (Stone et al., 2008; Evans et al., 2014). It is important to consider that MFPR is not without medical and psychological risks and that the ethical framework of each individual will guide decision making (Evans and Britt, 2010). A discussion regarding the ethical and medical implications of MFPR should be undertaken with all patients prior to undergoing ART (American College of Obstetricians and Gynecologists, 2013).

Summary

Over the last three decades, advances in ART have helped countless infertile couples achieve parenthood. This has had the unintended consequence of causing an epidemic of multiple births, which are associated with maternal, fetal, and neonatal morbidity and mortality. The subsequent psychosocial and economic costs are significant.

Prematurity and Stillbirth

MATTHEW B. WALLENSTEIN, SUZAN L. CARMICHAEL, AND DAVID K. STEVENSON

KEY POINTS

- Preterm birth, defined as birth prior to 37 weeks' gestation, is the leading cause of under-five child mortality worldwide.
- Preterm birth can be spontaneous or medically indicated, in which cesarean delivery or induction of labor is performed to avoid the risks of continued pregnancy.
- Preterm birth and stillbirth have been associated with multiple risk factors, including demographic, environment, genetic, placental, nutritional, microbial, and infectious factors.
- Further study of these factors and their associated pathways may lead to discovery of more direct ways to control the biology of pregnancy and, ultimately, the prevention of preterm birth.

Preterm birth, defined as birth prior to 37 weeks' gestation, affects 15 million newborns every year (Blencowe et al., 2012). It is the leading cause of under-five child mortality worldwide and accounts for one million deaths annually (Liu et al., 2015). More than 11% percent of newborns in the United States are born preterm, the annual cost of which exceeds \$26 billion (Behrman and Butler, 2007). Among surviving infants, preterm birth is also a major cause of disability-adjusted life years due to lifelong neurologic and developmental sequelae (Murray et al., 2012). The rate of preterm birth increased dramatically in the late 20th century, from less than 7% in the 1960s to a peak of 12.8% in 2006. However, there has been a recent decline to 11.4% in 2013, likely caused by a reduction in indicated late preterm deliveries (Frey and Klebanoff, 2016).

Preterm birth can be spontaneous, in which labor starts too soon, or medically indicated, in which cesarean delivery or induction of labor is performed to avoid the risks of continued pregnancy to the mother or fetus, e.g., due to preeclampsia or intrauterine growth restriction. Another subtype of spontaneous preterm birth is associated with premature preterm rupture of membranes (PPROM), in which rupture of amniotic membranes occurs both prior to 37 weeks' gestation and prior to the onset of labor (Fig. 8.1). Approximately 45% of preterm births result from spontaneous preterm labor, 30% from medically indicated delivery, and 25% from PPRM (Ananth et al., 2005; Goldenberg et al., 2008b). The extent to which the etiologic pathways leading to each type of preterm delivery are distinct versus overlapping is uncertain. Etiologic differences also exist between early preterm birth (e.g., <28 weeks' gestation) and late preterm birth, although the definition

of “early” versus “late” preterm birth is somewhat arbitrary in the context of continuous gestational progression.

Spontaneous preterm birth is an exceedingly complex phenomenon that is not well understood. Preterm labor and labor at term are both characterized by uterine contractions that eventually lead to delivery of a human newborn but the underlying factors that initiate them may differ (Romero et al., 2006, 2014a). Physiologic or disease processes that induce uterine contractility, cervical dilatation, or rupture of amniotic membranes prior to 37 weeks' gestation can lead to preterm birth (Fig. 8.2). There is evidence that spontaneous preterm birth may be related to perturbations in the maternal–fetal environment, such as abnormal placental development, infection, uterine overdistension, and inflammation. The biology underlying these disease states is just now being addressed (Schober et al., 2012; Chatenoud, 2014; Gaudilliere, 2015; Schumacher and Zenclussen, 2014). However, the factors associated with the majority of preterm births remain unexplained (Muglia and Katz, 2010; Wallenstein et al., 2016a).

In most mammalian species, progesterone plays a vital role in maternal–fetal tolerance during pregnancy and functions to prevent pathologic (early) onset of labor. Humans, however, have evolved to retain an elevated progesterone level until after delivery, meaning that a functional withdrawal of progesterone (i.e., loss of sensitivity to progesterone) appears to play an important role in the onset of parturition at term (Druckmann and Druckmann, 2005). Progesterone also plays an important role in modulation of the maternal immune system via alteration in the production of inflammatory and anti-inflammatory cytokines (e.g., tumor necrosis factor- α and interleukin-10) and inhibition of natural killer cell activity (Druckmann and Druckmann, 2005). These immunologic cascades are vital for maternal tolerance of the “semi-allograft” fetus (Trowsdale and Betz, 2006), as is also demonstrated by the prevention of preterm birth by exogenous progesterone (da Fonseca et al., 2003). Studies of biologic markers in blood and amniotic/vaginal fluid have identified several unique biologic signatures, such as inflammatory cytokines, that reflect these pathways related to preterm birth (Moawad et al., 2002; Goldenberg et al., 2005; Jelliffe-Pawlowski et al., 2013, 2014; Wallenstein et al., 2016b), but a complete understanding of the immunologic and inflammatory pathways of pregnancy remains elusive.

Spontaneous preterm birth is a predominantly human phenomenon, which is the result of evolutionary pressures to maintain the advantages of bipedal ambulation and high intelligence (Wittman and Wall, 2007). Human head size at birth is near the dimensional limit of what is physically possible for delivery through the maternal pelvis. The competing interests of intelligence (i.e.,

head size) and bipedal ambulation (i.e., narrow pelvis) probably led to adjustments in gene expression and biologic signaling pathways that steered the earlier timing of parturition for humans, leading to the programmed delivery of relatively immature fetuses, compared with other nonhuman mammals. This alteration in timing of delivery has left us with a more easily perturbed physiology of parturition and, as a result, preterm birth. Over the course of human evolution, the risk of lethal immaturity was of little consequence relative to the gains of easy ambulation and high intelligence for the majority of the human species, which is likely why the risk of preterm birth has persisted and now remains a global problem of epidemic proportions.

• **Fig. 8.1** Obstetric Precursors of Preterm Birth. (From Goldenberg RL, Culhane JF, Iams JD, Romero R. Epidemiology and causes of preterm birth. *Lancet*. 2008;371:75–84.)

Demographic Factors and Disparities

Multiple studies have demonstrated elevated risk of preterm birth among black women. The rate of preterm birth among blacks is as high as 18%, compared with 11% in the general US population. It is even more disparate for early preterm birth (<28 weeks' gestation), which is up to 3–4 times higher (Goldenberg et al., 1996a; Messer et al., 2008). Elevated risk remains after controlling for socioeconomic status and psychosocial risk factors, which themselves are associated with preterm birth (Lobel et al., 1992; Copper et al., 1996; Ananth et al., 2001; Braveman et al., 2015). Disparities are more modest to nonexistent for Hispanic women, despite social disadvantage within this group (Goldenberg et al., 2008b). Other studies have found that the rate of preterm birth varies greatly based on geographic location and is driven by socioeconomic and demographic characteristics of those locales but possibly less so for blacks than whites (Hamilton et al., 2013; Carmichael et al., 2014; Byrnes et al., 2015). Other factors associated with lower socioeconomic status, including educational background, extremes of maternal age, short interval between pregnancies (<6 months), and single marital status, have been independently associated with preterm birth (Brett et al., 1997; Smith et al., 2003, 2007; Conde-Agudelo et al., 2006; Thompson et al., 2006; Wong et al., 2016).

Some portion of the racial/ethnic and socioeconomic disparities can be explained by increased psychosocial stress among these populations (Kramer et al., 2011). Several studies have found that maternal stress, as measured by a survey of life events and/or biomarkers of activation of the hypothalamic–pituitary–adrenal axis, is also strongly associated with preterm birth (Stillerman et al., 2008; Holzman et al., 2009; Shaw et al., 2014b). However, interventions to reduce stress have had limited success in preventing preterm birth (Khianman et al., 2012). Other factors proposed to contribute to disparities include nutrient deficiencies and infection, although further research is needed to clarify their roles (Dunlop et al., 2011; Menon et al., 2011).

• **Fig. 8.2** Proposed Mechanisms of Disease Implicated in Spontaneous Preterm Labor. (From Romero R, Hassan SS, Gajer P, et al. The vaginal microbiota of pregnant women who subsequently have spontaneous preterm labor and delivery and those with a normal delivery at term. *Microbiome*. 2014;2:18. doi: 10.1186/2049-2618-2-18.)

Environmental Factors

Exposure to toxins – both self-inflicted and environmental – has been shown to increase the risk of preterm birth. Tobacco smoking during pregnancy is one of the most significant of those toxins (Andres and Day, 2000; Cnattingius, 2004). The mechanism is unclear but may involve systemic inflammation (leading to spontaneous preterm birth) or placental vasoconstriction from nicotine causing fetal growth restriction, which, in turn, may lead to an indicated preterm birth (Goldenberg et al., 2008b). Alcohol has not been consistently related to risk of preterm birth, although cocaine and other illicit substances increase preterm birth risk, likely via alteration of placental blood flow and/or placental abruption (Janisse et al., 2014).

Environmental air pollution has also been associated with increased risk of preterm birth. There are a myriad of air pollutants that have been investigated, including ozone, carbon monoxide, sulfur dioxide, and lead, among others (Padula et al., 2014a, 2014b; Stillerman et al., 2008).

Exposure to other toxicants, including various pesticides and heavy metals, has also been associated with preterm birth (Harley et al., 2011; Shachar et al., 2013).

Nutrition and Maternal Body Weight

Obesity, defined as body mass index (BMI) greater than or equal to 30 kg/m², is a major global health problem, affecting hundreds of millions of people worldwide. Prepregnancy obesity is a known risk factor for preterm birth (Wise et al., 2010; Djelantik et al., 2012; Gould et al., 2014; Shaw et al., 2014a). Comorbidities associated with obesity, such as diabetes and hypertension, may contribute to this obesity–preterm birth association (Sibai et al., 2000; Hedderson et al., 2003; Metzger et al., 2008). The biologic mechanisms behind the association may involve pathologic inflammation and altered vascular development (Mohamed-Ali et al., 1999; Visser et al., 1999; Royblat et al., 2000; Wallenstein et al., 2016b).

Low maternal BMI is also a risk factor for spontaneous preterm birth (Hendler et al., 2005). Poor nutrient intake is associated with both low and high BMI and serves as one potential explanation for their association with preterm birth. Iron deficiency anemia, lower intakes of nutrients such as folic acid and other B vitamins, zinc, calcium, magnesium, and polyunsaturated fatty acids, and higher dietary glycemic index have all also been associated with an increased risk (Kramer et al., 2009; Dunlop et al., 2011; Carmichael et al., 2013).

Infection and Microbiota

More than one-fourth of preterm births can be attributed to intra-amniotic infection, in which microorganisms perturb maternal–fetal homeostasis and trigger a cascade of biologic signals that initiate spontaneous preterm labor, PPROM, or fetal distress that leads to indicated preterm delivery (Romero et al., 2001; Elovitz et al., 2003; Menon and Furtunato, 2007; Moore et al., 2007; Agrawal and Hirsch, 2012). Microorganisms and their immunogenic cellular components activate toll-like receptors, chemokines, and cytokines, which tips the balance of maternal–fetal tolerance and leads to uterine contractility, rupture of amniotic membranes, and preterm delivery (Goldenberg et al., 2000; Romero et al., 2006). This may represent an evolutionary defense, as expulsion of an infected fetal–placental unit may allow the mother to survive and reproduce at a later time. Spontaneous preterm

births associated with chorioamnionitis are more common in women who deliver at earlier gestational periods (Hendler et al., 2005; Scholl, 2005).

The role of microorganisms in preterm birth is often subclinical, in which there are no signs or symptoms of overt maternal infection. One study showed that more than one-fifth of preterm newborns have umbilical cords colonized by *Mycoplasma* species (Goldenberg et al., 2008a). Bacterial vaginosis, which may affect up to one-third of pregnancies, has also been associated with preterm birth, particularly among black women (Hillier et al., 1995; Meis et al., 1995; Goldenberg et al., 1996b), as have sexually transmitted infections (Donders et al., 1993). Other infectious processes, such as periodontal disease and urinary tract infections, may also increase the risk of preterm birth (Offenbacher et al., 1996; Goldenberg et al., 2005). Unfortunately, however, treatment of these infections has not reduced the rate of preterm birth, including treatment for periodontal disease and bacterial vaginosis, among others (Kekki et al., 2001; Boggess, 2010).

There is also evidence that the microbiome, and perturbations therein, plays an important role in maternal–fetal tolerance and preterm birth (Romero et al., 2014b; DiGiulio et al., 2015; Gaudilliere, 2015). Recent technologic advances have enabled sequencing and amplification of DNA from myriad microbial communities, including the placental microbiome, revealing complex potential interactions between these microbial communities and clinical pregnancy outcomes (Aagaard et al., 2014). Study of microbial communities during pregnancy, and microbiota in general, represents an important and exciting frontier in the effort to further our understanding of preterm birth.

Genetic Factors

Preterm birth tends to run in families and appears to be inherited across generations (Porter et al., 1997; Winkvist et al., 1998). The heritability of preterm birth has been estimated to be 15%–40% (Muglia and Katz, 2010). Women with a prior history of preterm birth have more than a twofold increased risk of preterm birth in the subsequent pregnancy, although environmental factors may also explain this finding (Mercer et al., 1999).

Advances in our ability to conduct genome-wide association studies – and to do so in a cost-effective manner – have led to increased interest in the study of single-nucleotide polymorphisms. Several large genome-wide association studies were recently conducted and found no definitive evidence of association between preterm birth and any one single nucleotide polymorphism (Uzun et al., 2013; Zhang et al., 2015). However, additional analyses suggest that gene–gene interactions, particularly those related to inflammation and metabolic disorders, may affect the risk of preterm birth (Uzun et al., 2013). Several candidate genes have been identified by other investigators (Crider et al., 2005; Engel et al., 2005; Menon et al., 2006), but there are many inconsistencies in the data and findings (Plunkett and Muglia, 2008).

These inconsistencies may arise from the complex gene–gene and gene–environment interactions related to preterm labor and/or delivery (Ward et al., 2005; Plunkett and Muglia, 2008; Plunkett et al., 2009). One study found an association between a tumor necrosis factor- α allele, bacterial vaginosis, and preterm birth, although neither maternal carrier status nor bacterial vaginosis alone was associated with preterm birth (Macones et al., 2004). Similar interactions with bacterial vaginosis were reported in a recent study on maternal carrier status of an interleukin-6 allele among black women (Engel et al., 2005). As we refine our ability

to conduct genetic and epigenetic research, and to do so more affordably, we will continue to take incremental steps toward solving the puzzle of preterm birth.

Placental and Pregnancy Factors

Several factors associated with disruption of the uterine environment during pregnancy have been associated with preterm birth (Romero et al., 2014a). Abnormal vascular development of the placenta is a frequent occurrence among women who deliver before term (Kim et al., 2003). Perturbations of placentation may also account for many other adverse pregnancy outcomes that are seen in clinical practice, and that often cooccur with preterm birth, such as intrauterine growth restriction and preeclampsia (Cha et al., 2012). Vaginal bleeding, isolated or associated with placental abruption or placenta previa, also carries increased risk of preterm delivery (Krupa et al., 2006).

Overdistension of the uterus, caused by multiple gestation or polyhydramnios, substantially increases the risk of preterm birth (Williams et al., 1991; Kiely, 1998; Han et al., 2001). More than half of twin pregnancies result in delivery prior to 37 weeks' gestation, likely because of mechanical distension from increased fetal mass and other comorbidities associated with multiple gestation. Polyhydramnios and oligohydramnios are both risk factors for PPRM and preterm labor (Goldenberg et al., 2008). Anatomic abnormalities of the uterus and previous uterine or cervical surgical intervention also increase the risk of preterm birth (Jakobsson et al., 2007). Likewise, short cervix and cervical insufficiency carry increased risk, which varies greatly depending on degree of shortening (Copper et al., 1990; Iams et al., 1996; Andrews et al., 2000).

Prevention of Preterm Birth

Efforts to prevent – and to predict – preterm birth have largely failed, although several targeted interventions, including low-dose aspirin and 17-hydroxyprogesterone, have been shown to reduce the risk of preterm birth among women at high risk for adverse pregnancy outcomes, such as women with a personal history of preterm birth or stillbirth (da Fonseca et al., 2003; Meis et al., 2003; Henderson et al., 2014). Use of cervical cerclage among patients with short cervix and a history of preterm birth has effectively reduced the risk of preterm birth among this small subset of women (Iams et al., 2008). Population-level interventions that address underlying disparities, such as improving access to prenatal care, or other public policies related to smoking cessation or environmental pollution, may reduce the overall rate of preterm birth.

Other obstetrical interventions have been successful at mitigating the neonatal morbidity and mortality associated with preterm birth, such as antibiotics, antenatal betamethasone, magnesium sulfate, and tocolytic agents, but these interventions rarely prevent delivery prior to 37 weeks' gestation.

Stillbirth

Stillbirth, defined here as in utero death of a fetus at 20 weeks' gestation or later, is more common than most people realize. In the United States, more babies die in utero than die in the neonatal period. Stillbirths affect 5–6 per 1000 pregnancies in the United States, and the prevalence is several times higher in lower-income countries. For comparison, overall annual noninfant mortality is 8 per 1000 people in the United States (Hoyert et al., 2012). In recent decades, stillbirths have declined, but these gains are largely

attributable to improvements in obstetric care and prevention of intrapartum complications, and they are confined to later stillbirths (>28 weeks) (MacDorman and Kirmeyer, 2009). Despite its huge impact, little research has focused on finding causes of stillbirth, thus severely limiting opportunities for prevention (Lawn et al., 2011).

Over 80% of stillbirths are delivered before 37 weeks' gestation, and at least half of those fetuses are growth-restricted. In addition, at the earliest gestational ages, a large proportion of all deliveries (i.e., live births plus stillbirths) are stillbirths; for example, among deliveries at less than 28 weeks' gestation in California, about one-third are defined as stillbirths. Given these overlaps, we also expect overlaps in the etiologies of stillbirth, preterm delivery, and growth restriction. Indeed, all of these outcomes share similar risk factors, including chronic maternal medical conditions such as obesity, hypertension and diabetes, maternal stress, and a marked black–white disparity (Willinger et al., 2009; Fretts, 2010; Hogue et al., 2013; Warland and Mitchell, 2014; Yao et al., 2014; Carmichael et al., 2015). In addition, some of the most common clinical antecedents of stillbirth are similar to those of preterm delivery, such as spontaneous preterm labor or rupture of membranes, infection, and placental insufficiency. Inflammation may be a shared pathway contributing to stillbirth and preterm delivery (Fretts, 2010; Mullins et al., 2012; Warland and Mitchell, 2014). Further understanding of preterm birth will likely provide clues to help us understand stillbirth. More frequent inclusion of stillbirth in studies of preterm delivery – especially early preterm delivery – will be important to fully understanding either outcome.

Looking Forward

Multiple causal pathways likely lead to preterm birth and stillbirth. Further study of these pathways may lead to discovery of more direct ways to control the biology of pregnancy. Preliminary evidence already exists for effective prevention of preterm birth through interference with some of these pathways (Henderson et al., 2014). Future interventions may take the form of targeted pharmaceuticals, such as low-dose aspirin, or through community-based interventions that indirectly affect the biology, such as implementation of policies related to socioeconomic disparities or nutrition. Understanding when and where we are able to intervene to prevent preterm birth will require collaboration on large and transdisciplinary scales with concomitant integration of data from multiple levels of inquiry (Stevenson et al., 2013).

Nonimmune Hydrops

SCOTT A. LORCH AND THOMAS J. MOLLEN

KEY POINTS

- Nonimmune hydrops fetalis results from many etiologies.
- Management involves correcting the underlying cause.
- The condition is associated with significant morbidity and mortality.
- Some etiologies are amenable to treatment in utero.

A newborn with hydrops has an abnormal accumulation of fluid. The condition varies from mild, generalized edema to massive anasarca with effusions in multiple body cavities and with peripheral edema so severe that the extremities are fixed in extension. Fetuses with severe hydrops may die in utero; if liveborn, they may die in the neonatal period from the severity of their underlying disease or from severe cardiorespiratory failure.

The first description of hydrops, in a newborn twin, may have appeared in 1609 (Liley et al., 2009). Ballantyne (1892) suggested that the finding of hydrops was an outcome from many different causes, in contrast to the belief at that time that hydrops was a single entity. Potter (1943) was the first to make the distinction between nonimmune hydrops and hydrops secondary to erythroblastosis fetalis by describing a group of infants with generalized body edema who did not have hepatosplenomegaly or abnormal erythropoiesis. Potter's description of more than 100 cases of hydrops included two sets of twins in which one had hydrops and the other did not, thus presenting the first description of twin–twin transfusion syndrome. With the nearly universal use of anti-D globulin and refinement of the schedule and doses for its administration, the occurrence of immune-mediated hydrops has steadily declined and may be as low as 6%–10% of all cases of hydrops (Bellini et al., 2015).

Incidence

The reported incidence of nonimmune hydrops in the general population has been highly variable, ranging from 6 per 1000 pregnancies in a high-risk referral clinic in the United Kingdom between 1993 and 1999 (Sohan et al., 2001), to 1 in 4000 pregnancies (Norton, 1994); other published rates are 6 per 1000 pregnancies (Santolaya et al., 1992), 1.3 per 1000 pregnancies (Wafelman et al., 1999), and 1 per 1700 pregnancies (Heinonen et al., 2000). However, all the published studies come from single institutions, with the at-risk populations ranging from that of a high-risk

pregnancy clinic to infants in a neonatal intensive care unit and generally predating the more routine use of ultrasound investigation in the late first trimester of pregnancy (Iskaros et al., 1997). There have been no recent studies of the prevalence of this condition in all pregnant women in one geographic area to calculate the true population incidence of nonimmune hydrops, especially monitoring fetuses who died in utero. Geography also affects the incidence; several causes of nonimmune hydrops, such as α -thalassemia, are more common in certain areas of the world.

Etiology

Nonimmune hydrops has been associated with a wide range of conditions (Table 9.1). In many of these conditions, edema formation results from one of the following possible processes:

- Elevated central venous pressure (CVP), in which the cardiac output is less than the rate of venous return
- Anemia, resulting in high-output cardiac failure
- Decreased lymphatic flow
- Capillary leak

The actual pathophysiology of hydrops for many of the conditions in Table 9.1, however, is still not understood.

The most common causes of nonimmune hydrops are chromosomal, cardiovascular, hematologic, thoracic, infectious, and conditions related to twinning (Wilkins, 1999; Abrams et al., 2007; Bellini et al., 2009a). As with reported incidence rates, the relative contribution of these causes varies by study. The studies that focus on early fetal presentation of hydrops (postconceptional age of less than 24 weeks' gestation) have found that chromosomal abnormalities, such as Turner syndrome and trisomies 13, 18, and 21, contribute 32%–78% of all cases of hydrops (Boyd and Keeling, 1992; McCoy et al., 1995; Iskaros et al., 1997; Heinonen et al., 2000; Sohan et al., 2001). For fetuses whose hydrops becomes evident after 24 weeks' gestation, cardiovascular and thoracic causes are most prevalent, with rates ranging between 30% and 50% (Machin, 1989; McCoy et al., 1995). Studies from Asia have noted a higher percentage of cases from hematologic causes, probably because of the higher rates of α -thalassemia in the population (Lin et al., 1991; Nakayama et al., 1999).

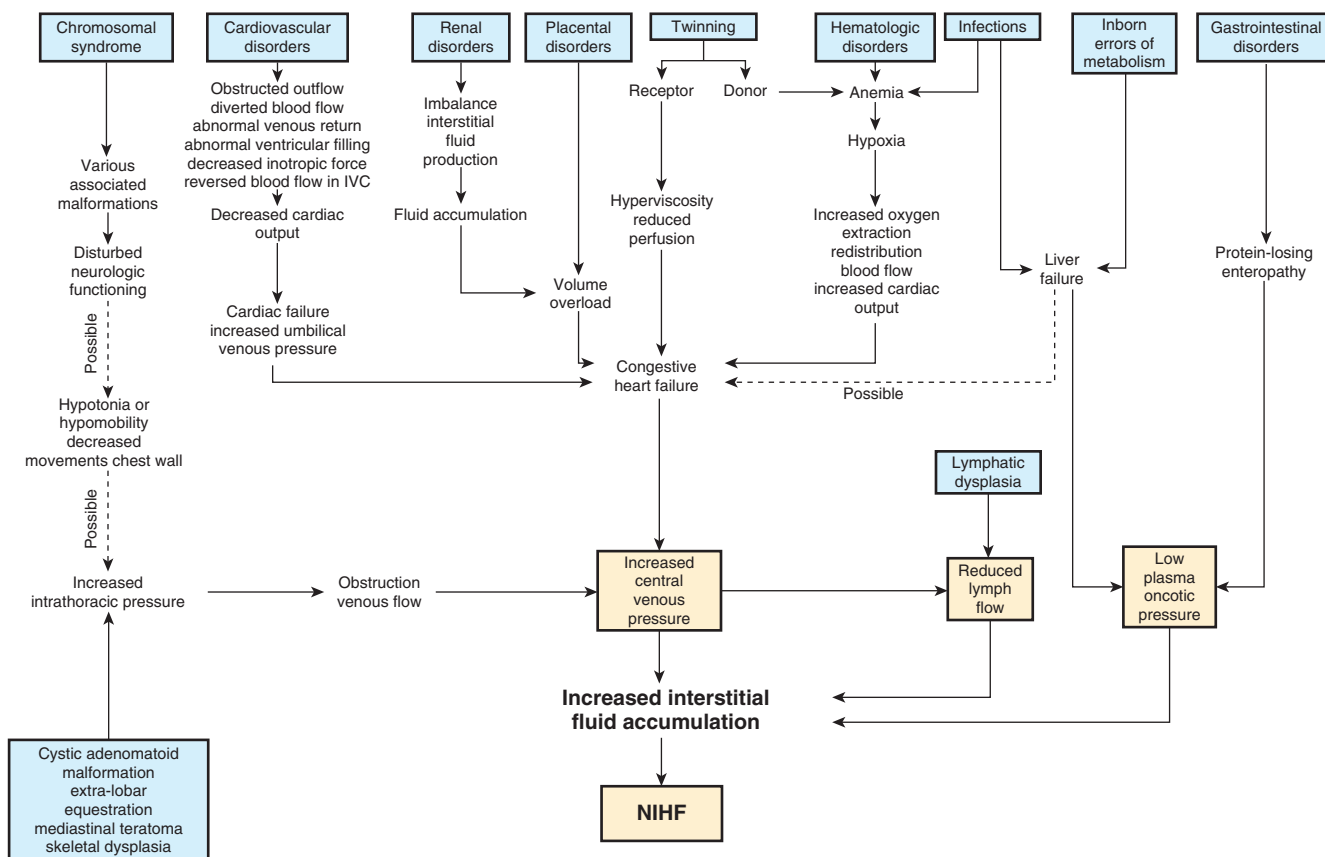

A recent review of studies published between 2008 and 2013 suggests a potential change in the etiologies of nonimmune hydrops, when compared with studies published between 1979 and 2008 (Bellini et al., 2015). These more recent studies reported a higher rate of lymphatic etiologies (15.0% compared with 5.7% in older

TABLE 9.1 Conditions Associated With Hydrops Fetalis

| Condition Type | Specific Conditions | Condition Type | Specific Conditions |
|-------------------------|---|----------------------------------|---|
| Hemolytic anemias | Alloimmune, Rh, Kell, α -chain hemoglobinopathies (homozygous α -thalassemia) Red blood cell enzyme deficiencies (glucose phosphate isomerase deficiency, glucose-6-phosphate dehydrogenase) | Pulmonary conditions | Cystic adenomatoid malformation of the lung Mediastinal teratoma Diaphragmatic hernia Lung sequestration syndrome Lymphangiectasia |
| Other anemias | Fetomaternal hemorrhage Twin–twin transfusion Diamond–Blackfan | Renal conditions | Urinary ascites Congenital nephrosis Renal vein thrombosis Invasive processes and storage disorders Tuberous sclerosis Gaucher disease Mucopolysaccharidosis Mucopolipidosis |
| Cardiac conditions | Premature closure of foramen ovale Ebstein anomaly Hypoplastic left or right heart Subaortic stenosis with fibroelastosis Cardiomyopathy, myocardial fibroelastosis Atrioventricular canal Myocarditis Right atrial hemangioma Intracardiac hamartoma or fibroma Tuberous sclerosis with cardiac rhabdomyoma | Chromosome abnormalities | Trisomy 13, trisomy 18, trisomy 21 Turner syndrome 46, XX/XY chimerism |
| Cardiac arrhythmias | Supraventricular tachycardia Atrial flutter Congenital heart block | Bone diseases | Osteogenesis imperfecta Achondroplasia Asphyxiating thoracic dystrophy |
| Vascular malformations | Hemangioma of the liver Any large arteriovenous malformation Klippel–Trénaunay syndrome Idiopathic infantile arterial calcification | Gastrointestinal conditions | Bowel obstruction with perforation and meconium peritonitis Small bowel volvulus Other intestinal obstructions Prune-belly syndrome |
| Vascular accidents | Thrombosis of umbilical vein or inferior vena cava Recipient in twin–twin transfusion | Tumors | Neuroblastoma Choriocarcinoma Sacrococcygeal teratoma Hemangioma or other hepatic tumors Congenital leukemia Cardiac tumors Renal tumors |
| Infections | Cytomegalovirus, congenital hepatitis, human parvovirus, enterovirus, other viruses Toxoplasmosis, Chagas disease Coxsackie virus Syphilis Leptospirosis | Maternal or placental conditions | Maternal diabetes Maternal therapy with indomethacin Multiple gestation with parasitic fetus Chorioangioma of placenta, chorionic vessels, or umbilical vessels Toxemia Systemic lupus erythematosus |
| Lymphatic abnormalities | Congenital lymphatic dysplasia Lymphatic malformations Lymphangiectasia Cystic hygroma Noonan syndrome Multiple pterygium syndrome Congenital chylothorax Hereditary lymphedema type 1 | Miscellaneous | Neu–Laxova syndrome Myotonic dystrophy Hereditary lymphedema type 1 |
| Nervous system lesions | Absence of corpus callosum Encephalocele Cerebral arteriovenous malformation Intracranial hemorrhage (massive) Holoprosencephaly Fetal akinesia sequence | Idiopathic | |

studies) and a lower rate of thoracic or chromosomal etiologies. Idiopathic hydrops, or hydrops of unknown etiology, remained constant at between 18% and 20% of all cases. As with older studies, papers published between 2008 and 2013 varied widely in the prevalence of specific etiologies depending on the ability of the clinicians to complete their diagnostic evaluation, geography, and the inclusion of fetal deaths in the analysis (Machin, 1989;

Santolaya et al., 1992; McCoy et al., 1995; Iskaros et al., 1997; Yaegashi et al., 1998; Nakayama et al., 1999; Wafelman et al., 1999; Wy et al., 1999; Heinonen et al., 2000; Sohan et al., 2001; Bellini et al., 2009b). It is likely that with increased understanding of (and genetic testing for) many of the conditions listed in Table 9.1, the number of infants diagnosed with idiopathic, nonimmune hydrops will continue to decline.

• **Fig. 9.1** Impact of Various Etiologies for Nonimmune Hydrops on Fluid Homeostasis. IVC, Inferior vena cava; NIHF, nonimmune hydrops fetalis. (Modified from Bellini C, Hennekam RCM. Non-immune hydrops fetalis: a short review of etiology and pathophysiology. *Am J Med Genet A*. 2012;158A: 597–605.)

Pathophysiology

Normal Fluid Homeostasis

Abnormal body fluid homeostasis is the underlying cause of edema, whether localized or generalized. To understand the pathogenesis of hydrops, the clinician must consider the forces underlying normal fluid homeostasis that underpin a general pathophysiologic pathway for this disorder (Fig. 9.1) as proposed by Bellini and Hennekam (2012). The regulation of net fluid movement across a capillary membrane depends on the Starling forces, which were first described by E. H. Starling (1896). Flow between intravascular and interstitial fluid compartments is determined by the balance among (1) capillary hydrostatic pressure, (2) serum colloid oncotic pressure, (3) interstitial hydrostatic pressure or tissue turgor pressure, and (4) interstitial osmotic pressure, which depends on lymphatic flow. The Starling equation defines the relationship among these forces and their net effect on net fluid movement, or filtration, across a semipermeable membrane (such as the capillary membrane) as:

$$\text{Filtration} = K[(P_c - P_t) - R(O_p - O_t)]$$

where K = capillary filtration coefficient, representing the extent of permeability of a membrane to water and thus describing capillary integrity; P_c = capillary hydrostatic pressure; P_t = interstitial hydrostatic pressure or tissue turgor pressure; R = reflection coefficient for a solute, representing the extent of permeability of the capillary wall to that solute; O_p = plasma oncotic pressure as

• **Fig. 9.2** Starling Forces and Net Effect on Fluid Homeostasis. Arrows represent net effect of movement of fluid across the capillary membrane for each factor under normal conditions. P_c , Capillary hydrostatic pressure; P_t , interstitial hydrostatic pressure or tissue turgor pressure; O_p , plasma oncotic pressure as determined by plasma proteins and other solutes; O_t , interstitial osmotic pressure.

determined by plasma proteins and other solutes; and O_t = interstitial osmotic pressure (Fig. 9.2).

Although an abnormality of any of the components of this equation may, in theory, result in the accumulation of edema fluid, the fetal-placental unit presents a unique physiologic condition that effectively eliminates two of the factors, assuming unimpeded fetal-placental flow and an appropriately functioning maternal-placental interface. Because approximately 40% of fetal cardiac output is allocated to the placenta, there is rapid transport

of water between the fetus and mother. Any condition resulting in elevated fetal capillary hydrostatic pressure or low plasma colloid oncotic pressure would likely cause the net flow of water from fetal villi in the placenta to the maternal blood stream, where it can be effectively eliminated. This elimination of fluid would counteract the accumulation of interstitial fluid by the fetus. Although the placenta of a fetus with hydrops is also edematous, these changes are believed to occur with, and not before, fetal fluid accumulation.

Derangements in Fluid Homeostasis

Elevated Central Venous Pressure

The most commonly diagnosed causes of nonimmune hydrops that appear in fetuses older than 24 weeks' gestation are cardiac disorders. Any state in which cardiac output is lower than the rate of venous return results in an elevated CVP that raises capillary filtration pressures and, if high enough, restricts lymphatic return. Both of these mechanisms may then contribute to interstitial accumulation of fluid. Structural cardiac causes of elevated CVP include right-sided obstructive lesions and valvular regurgitation. The most common and easily reversible cause of nonimmune hydrops is supraventricular tachycardia (SVT). In general, cardiac output rises with heart rate. At the increasingly high rates seen in SVT, however, cardiac output plateaus and then diminishes. The heart rates observed with SVT are often associated with decreased cardiac output. Impaired cardiac output results in elevated CVP, which can give rise to edema through mechanisms discussed previously (Gest et al., 1990).

Infants with alloimmune hydrops (and several of the nonimmune hydrops conditions as well) have significant anemia that may also result in elevated CVP. It has been proposed that anemia leads to congestive heart failure with increased hydrostatic pressure in the capillaries, causing vascular damage that results in edema. However, the hematocrit values of infants with and without hydrops overlap significantly, suggesting that anemia alone is not the only explanation. A rapidly lowered hemoglobin concentration results in greater cardiac output to maintain adequate oxygen delivery. This increased cardiac output results in higher oxygen demands by the myocardium, which may be difficult to meet because of the anemia. The hypoxic myocardium can become less contractile and less compliant, with ventricular stiffness causing increased afterload to the atria. High-output congestive heart failure may then develop, resulting in elevated CVP. Raised CVP leads to increased capillary filtration pressures and impairment of lymphatic return (Weiner, 1993).

An intrathoracic mass such as a pulmonary malformation may also increase CVP, resulting in impaired filling of the right ventricle and consequent increased capillary hydrostatic pressure. While the underlying reason for the elevated CVP differs between these two conditions, the resulting clinical conditions are similar.

Decreased Lymphatic Flow

If the rate of fluid filtration from plasma to tissues exceeds the rate of lymph return to the central venous system, then edema and effusions may form. A structural impediment or increased CVP that opposes lymphatic return to the heart can impair lymph flow. Recent advances in the radiographic evaluation of the lymphatic system, using magnetic resonance imaging (MRI) and lymphangiography, have improved the assessment of this system. To determine the effects of alterations in CVP on lymphatic return, Gest et al. (1992) inserted a catheter into the thoracic duct of fetal lambs and applied an opposing hydrostatic pressure by varying

the height of the catheter. Thoracic duct flow was nearly constant over the physiologic range of CVP but sharply decreased at elevated pressures; therefore lymphatic flow may be reduced or essentially blocked in pathologic states associated with elevated CVP.

Decreased Oncotic Pressure

A third potential etiology for nonimmune hydrops is hypoalbuminemia. The most convincing evidence for this etiology is in conditions where reduced compliance of a right ventricle may result in flow reversal in the inferior vena cava, which may in turn cause end-organ damage to the liver, with consequent hypoalbuminemia and portal hypertension enhancing formation of both edema and ascites. Hydrops has been produced in fetal lambs (Blair et al., 1994) in which the hemoglobin content was lowered in 12 fetuses through exchange transfusion using cell-free plasma; six became hypoproteinemic. Anemia developed more rapidly with a higher CVP in fetuses with hydrops than in the fetuses without hydrops. In the most severely anemic fetuses, it is probable that decreased oxygen transport causes tissue hypoxia, which in turn increases capillary permeability to both water and protein. These changes in capillary permeability may contribute to the development of hydrops.

However, human fetuses with hypoproteinemia as a result of nephrotic syndrome or analbuminemia rarely experience hydrops, supporting the hypothesis that hypoproteinemia alone is not sufficient to cause hydrops. To elucidate the role of isolated hypoproteinemia in the genesis of hydrops, Moise et al. (1991) induced hypoproteinemia in sets of twin fetal lambs. One twin from each set underwent serum protein reduction through repeated removal of plasma and replacement with normal saline; the other twin served as the control. Over 3 days, plasma protein concentrations were reduced by an average of 41%, with a 44% reduction in colloid osmotic pressure, in experimental subjects. No fetal animals became edematous, and total body water content values were similar in experimental and control animals. Thus hypoproteinemia alone was insufficient to cause hydrops fetalis over the course of the study. Transcapillary filtration probably increased with hypoproteinemia but was compensated for by lymphatic return. Hypoproteinemia may lower the threshold for edema formation in the presence of impaired lymphatic return or increased intravascular hydrostatic pressures.

Increased Capillary Leak

One final potential etiology for hydrops is increased capillary leak. Increased capillary leak is typically identified not as a primary mechanism for hydrops, but as part of the pathway between nonimmune hydrops and other insults, such as infection, hypoxic injury, or increased capillary hydrostatic pressure seen with elevated CVP or decreased lymphatic flow (Bellini and Hennekam, 2012).

Prenatal Diagnosis

Despite the underlying cause of hydrops or the clinical presentation, the prenatal diagnosis is made via the ultrasonographic finding of excess fluid in the form of ascites, pleural or pericardial effusions, skin edema, placental edema, or polyhydramnios. Several definitions for ultrasonographic diagnosis based on quantity and distribution of excess fluid have been proposed. One widely accepted set of criteria consists of the presence of excess fluid in any two of the previously listed compartments. A recent study suggests that the involvement of more body compartments is associated with higher mortality (Kim et al., 2015). Because this definition is based on

TABLE 9.2 Antenatal Investigation of Fetal Hydrops

| Area | Testing |

Prenatal diagnosis and management of nonimmune hydrops fetalis. *Aust N Z J Obstet Gynaecol.* 1999;39:285–290 and Bellini C, Hennekam RC, Bonioli E. A diagnostic flow chart for non-immune hydrops fetalis. *Am J Med Genet A.* 2009;149A:852–853.

the presence of excess fluid alone, the degree of severity is generally subjective.

Swain et al. (1999) and Bellini and Hennekam (2012) outline a multidisciplinary approach to the evaluation and management of the mother and fetus with hydrops. Table 9.2 provides recommendations for the investigation of fetal hydrops. Patient history should focus on ethnic background, familial history of consanguinity, genetic or congenital anomalies, and complications of pregnancy, including recent maternal illness and environmental exposures. Maternal disorders such as diabetes, systemic lupus erythematosus, myotonic dystrophy, and any type of liver disease should also be noted. Initial laboratory investigation includes blood typing and a Coombs test to rule out immune-mediated hydrops. Additional studies may include screening for hemoglobinopathies, a Kleihauer–Betke test

to eliminate fetal–maternal hemorrhage, and testing for TORCH (i.e., toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex), including syphilis and parvovirus B19.

Rapid evaluation is necessary to determine whether fetal intervention is possible and to estimate the prognosis for the fetus. Many conditions, such as arrhythmias, twin–twin transfusion, large vascular masses, and congenital diaphragmatic hernias and other chest-occupying lesions, are discovered during the initial ultrasonographic evaluation (Coleman et al., 2002). Middle cerebral artery peak systolic velocity measurement can aid in detecting the presence of fetal anemia (Hernandez-Andrade et al., 2004). If the initial ultrasonic examination is not helpful in identifying a cause, it may be helpful to repeat it at a later date to reassess fetal anatomy, monitor progression of the hydrops, and evaluate well-being of the fetus. Fetal MRI is being employed more commonly in cases of hydrops fetalis where the sonographic examination is unable to present a clear picture regarding etiology or to further delineate the anatomy in cases with a known anatomic etiology.

Fetal echocardiography should also be performed to evaluate for cardiac malformations and arrhythmia. Amniotic fluid can be obtained for fetal DNA analysis, cultures, and lecithin-to-sphingomyelin ratio to assess lung maturity. Fetal blood sampling allows for other tests, such as a complete blood cell count, routine chemical analyses, DNA analysis, bacterial and viral cultures, metabolic studies, and serum immunoglobulin measurements.

Prenatal Management

The goals of antenatal evaluation and management of fetal hydrops depend on the underlying cause. In diagnoses for which therapy is futile, the goal is to avoid unnecessary invasive testing and cesarean section. The prognosis should be discussed frankly with the parents, who should be given the option of terminating the pregnancy. If the underlying cause is amenable to fetal therapy, the risks and benefits of such therapy, as well as the warning that diagnostic error is possible, should be discussed with the family.

SVT is one of the most common known causes of nonimmune hydrops, and it is the most amenable to treatment (Newburger and Keane, 1979; Huhta, 2004). Usually the mother is given antiarrhythmic agents, and the fetus is monitored closely for resolution of the SVT. Digoxin is most commonly administered, although other antiarrhythmics have been used, such as sotalol or flecainide, because transplacental transfer of digoxin may be impaired in the setting of hydrops. In extreme circumstances, such as fetal tachyarrhythmia refractory to maternal treatment, direct fetal administration of antiarrhythmic agents via percutaneous umbilical blood sampling or intramuscular injection, although untested and highly risky, has met with some success.

If anemia is the cause of hydrops, transfusions of packed red blood cells may be administered to the fetus. Often a single transfusion reverses the edema, although serial transfusions may be necessary. Parvovirus B19 (Anand et al., 1987) and fetal–maternal hemorrhage are examples of diagnoses that are amenable to this therapy. Transfusions should be given, with the use of ultrasonographic guidance, into the intraperitoneal space or umbilical vein. Blood instilled into the abdominal cavity is taken up by lymphatics, but elevated CVP present in hydropic fetuses may impair this uptake. If uptake of intraperitoneal blood is incomplete, treatment for the hydrops is less successful. In addition, degeneration of the remaining hemoglobin may create a substantial bilirubin load, necessitating phototherapy or exchange transfusion after the fetus is delivered. Other diagnoses involving anemias that are refractory

to transfusions, such as α -thalassemia, may require neonatal stem cell transplantation.

High morbidity and mortality rates in severe twin–twin transfusion with associated hydrops led to multiple international trials of laser photocoagulation of interfetal vascular connections. A recent systematic review of 34 studies of 3868 patients published between 1990 and 2014 found improved survival comparing the 1990–1995 with the 2011–2014 epoch. Of pregnancies requiring laser photocoagulation, both twins survived in 65% of the pregnancies in the more recent epoch, with an additional 23% of pregnancies reporting a survival of one of the fetuses (Akkermans et al., 2015). However, the current level of evidence is limited in the reported effect on neurodevelopmental outcomes in survivors. The most recent Cochrane Review from 2008, then, recommends considering treatment with laser coagulation at all stages of twin–twin transfusion (Roberts et al., 2008).

Fetal intervention has met with some success in surgical defects and other conditions associated with hydrops (Adzick et al., 1998; Kitano et al., 1999; Azizkhan and Crombleholme, 2008). While fetal lung lesions such as congenital cystic adenomatoid malformation (CCAM) and pulmonary sequestration frequently involute and may disappear before delivery, in the most extreme cases they can result in mediastinal shift, pulmonary hypoplasia, cardiovascular compromise, and hydrops. The highest risk lesions for the development of hydrops include those lesions with a CCAM volume ratio greater than 2, an everted hemidiaphragm or a mass-to-thorax ratio greater than 0.56 (Vu et al., 2007; Cass et al., 2011). Early surgical resection for these most severe lesions has occurred in several centers. The latest therapy involves ex utero intrapartum therapy, or EXIT delivery, where the resection of the CCAM occurs immediately after delivery but before separation of the placenta. Reported outcomes vary widely between centers. Thoracoamniotic shunts for large unicystic lesions and pleuroamniotic shunts for hydrothorax have reportedly enhanced survival in extreme cases. Similarly, in cases of massive urinary ascites, urinary diversion via peritoneal shunts has been reported.

There are complications associated with fetal interventions. Preterm birth can be as high as 80% under 37 weeks' gestation and 15% under 30 weeks' gestation, particularly for open surgical procedures (Adzick et al., 2011; Bennett et al., 2014). Maternal morbidities related to fetal intervention range from spontaneous and/or premature rupture of membranes, oligohydramnios, uterine wound infection with dehiscence to mild postoperative interstitial pulmonary edema, especially in mothers with longer operative times (Adzick et al., 2011; Pedreira et al., 2016; Peranteau and Adzick, 2016).

In cases in which the cause of hydrops can be corrected by appropriate care at the time of delivery, such as elimination of a chorioangioma, as well as those cases in which no cause can be ascertained, close observation for fetal demise is the focus of prenatal management. Many cases of nonimmune hydrops manifest in the third trimester as preterm labor. It is difficult to decide whether to attempt tocolysis and delay delivery so as to allow the potentially beneficial administration of steroids before birth or to deliver the fetus immediately. If tocolysis is possible, expectant management should include usual biophysical testing, although fetal decompensation may be difficult to assess. Abnormal fetal heart tracings, oligohydramnios, decreased fetal movement, and poor fetal tone are all ominous signs. Prolonging the pregnancy beyond attainment of a mature lung profile is not generally recommended, unless available evidence indicates improvement or resolution of the hydrops.

TABLE 9.3 Diagnostic Evaluation of Newborns With Nonimmune Hydrops

| System | Type of Evaluation |
|-----------------------|---|
| Cardiovascular | Echocardiogram, electrocardiogram |
| Pulmonary | Chest radiograph, pleural fluid examination |
| Hematologic | Complete blood cell count, differential platelet count, blood type and Coombs test, blood smear for morphologic analysis |
| Gastrointestinal | Abdominal radiograph, abdominal ultrasonography, liver function tests, peritoneal fluid examination, total protein and albumin levels |
| Renal | Urinalysis, blood urea nitrogen, and creatinine measurements |
| Genetic | Chromosomal analysis, skeletal radiographs, genetic consultation |
| Congenital infections | Viral cultures or serologic testing, including TORCH agents and parvovirus |
| Pathologic | Complete autopsy, placental examination |
| Lymphatic | MRI, lymphoscintigraphy, ICG lymphography |

Neonatal Evaluation

Table 9.3 summarizes the diagnostic evaluations recommended for newborns with nonimmune hydrops of unknown cause. There are a few key points:

- Prenatal results may help guide initial evaluation.
- Early cardiac and hematologic evaluations will determine most known etiologies.
- A multidisciplinary approach is essential.
- Response to interventions may help guide evaluation.

Intensive Care of the Infant With Hydrops Fetalis

After successful resuscitation, including intubation, administration of surfactant, and placement of umbilical catheters, the clinical management can address both the cause and the complications of hydrops. Morbidity and mortality may result from the hydropic state, the underlying conditions giving rise to hydrops, or both. A fetus with hydrops that is delivered prematurely is subject to the additional complications of prematurity. If there is massive ascites or pleural effusions, initial resuscitation may require thoracentesis or peritoneal tap. Because of pulmonary edema, newborns with hydrops are susceptible to pulmonary hemorrhage and may require high levels of positive end-expiratory pressure.

Respiratory Management

Virtually all neonates with hydrops require mechanical ventilation because of pleural and peritoneal effusions, pulmonary hypoplasia,

surfactant deficiency, pulmonary edema, poor chest wall compliance caused by edema, or persistent pulmonary hypertension of the newborn. The presence of persistent pleural effusions may necessitate the placement of chest tubes. Ascites may also compress the diaphragm and impair lung expansion. Breath sounds, chest wall movement, blood gas levels, and radiographs must all be monitored frequently so that ventilator support can be reduced in response to improvements in lung compliance and water clearance. Pneumothoraces and pulmonary interstitial emphysema remain potential complications as long as ventilator support is continued. Neonates who need a prolonged course of ventilation, particularly those born prematurely, may develop bronchopulmonary dysplasia. Chronic lung disease results in a longer and more complicated hospital course and contributes to the late mortality of neonatal hydrops.

Fluid and Electrolyte Management

A primary goal of fluid management is resolution of the hydrops itself. Maintenance fluids should be restricted, with volume boluses given only in response to clear signs of inadequate intravascular volume. The hydropic newborn has an excess of free extracellular water and sodium. Fluids given during resuscitation further increase the amount of water and sodium that must be removed during the immediate neonatal period. Initial maintenance fluids should contain minimal sodium. Serum and urine sodium levels, urine volume, and daily weights should be monitored carefully to guide administration of fluids and electrolytes. Urinary sodium levels may help differentiate between hyponatremia caused by hemodilution and urinary losses.

Cardiovascular Management

Hydropic infants may develop hypovolemia as a result of capillary leakage, poor vascular tone, impaired myocardial contractility from hypoxia or infection, impaired venous return caused by shifting or compression of mediastinal structures, and/or pericardial effusion. Thus these infants may present in shock. Adequate intravascular volume must be maintained, and correctable causes of impaired venous return should be addressed. Peripheral perfusion, heart rate, blood pressure, and acid–base status should be monitored carefully.

Lymphatic Evaluation and Interventions

Recent advances in the use of T2-weighted MRI, contrast-enhanced magnetic resonance lymphangiograms, and lymphangiography have identified a group of infants with nonimmune hydrops who have obstructive lymphatic systems. These infants, most of whom have congenital anomalies of the thoracic duct, may benefit from new procedures to relieve these obstructions (Gray et al., 2014; Schild et al., 2015). There are few studies in neonates, although data from older infants, many of whom had single-ventricle physiology, suggest that the use of percutaneous lymphatic interventions after a bilateral intranodal lymphangiogram may be useful in these infants (Itkin et al., 2011; Dori et al., 2014, 2016). Further work is needed in the neonatal population with nonimmune hydrops to identify those infants who may benefit from such interventions.

Clinical Course and Outcome

Despite improvements in diagnosis and management, mortality from nonimmune hydrops remains high. For example, a recent

study of 92 infants born with nonimmune hydrops between 2000 and 2012 reported a 45% fetal death rate and a 36% survival rate to 1 year (Ota et al., 2016). Other recent studies report survival rates between 20% and 30% (Moreno et al., 2013; Turgal et al., 2015).

The best predictors of survival are the cause of the hydrops, the gestational age of the child at delivery, and the condition of the neonate at birth. Highest survival rates are seen in infants with parvovirus infection, chylothorax, or SVT. The lowest survival rates are for hydrops associated with a chromosomal diagnosis, although the figures may be biased because a significant number of pregnancies in such cases are terminated (Heinonen et al., 2000; Sohan et al., 2001). A recent review of 598 patients with nonimmune hydrops found other risk factors for increased mortality, including younger gestational age, lower 5-minute Apgar score, and the need for increased respiratory support (Abrams et al., 2007). A smaller study from Taiwan also found that lower albumin levels were associated with a higher mortality rate (Huang et al., 2007).

Interventions to improve outcomes in hydrops are limited by the rarity of the disease. Most hydropic neonates lose a minimum of 15% of their birthweight, and some lose as much as 30%. Ordinarily, diuresis begins on the second or third day after birth and continues for a period of 2–4 days. Once the edema has resolved, the neonates have normal levels of circulating protein and eventually recover from their apparent capillary leak syndrome. No specific management strategies during the neonatal period, such as the use of high-frequency oscillatory ventilation, have been shown to improve outcome (Wy et al., 1999). However, extracorporeal membrane oxygenation may be a reasonable option for some infants with nonimmune hydrops, with one study showing a 54% survival rate in 28 cases (Bealer et al., 1997). More recent data have not been published.

For infants who survive the immediate neonatal period, long-term outcomes largely depend on the etiology of the condition. For example, an older study from Japan found that 13 of 19 surviving infants with nonimmune hydrops had normal development at 1–8 years (Nakayama et al., 1999). More recent data, though, found only a 45%–50% survival rate without developmental delay by 1 year (Fukushima et al., 2011; Ota et al., 2016). In both these studies, hydropic infants with mild or severe delays had other morbidities, such as extreme prematurity, structural cardiac lesions, or chromosomal anomalies. Thus similar to mortality, long-term morbidities from nonimmune hydrops appear to result from the underlying cause of the hydrops, gestational age at delivery, and complications arising immediately after delivery.

Maternal Diabetes

ZANE BROWN AND JUSTINE CHANG

KEY POINTS

- The incidence of diabetes in pregnancy is steadily rising, likely in parallel with the rising incidence of obesity among women of reproductive age.
- Women with diabetes are at increased risk for fetal complications (such as congenital malformations, fetal growth abnormalities, and stillbirth) and perinatal/neonatal complications (such as prematurity, respiratory distress, and metabolic abnormalities including hypoglycemia and electrolyte derangements).
- Good maternal glycemic control achieved preconception and maintained throughout pregnancy is key to optimizing fetal and neonatal outcomes.
- Breastfeeding should be strongly encouraged and supported as it may reduce some of the possible adverse effects of intrauterine programming in the context of maternal diabetes.

Diabetes mellitus is an increasingly common disorder in the United States and around the world. According to 2012 data from the US Centers for Disease Control and Prevention (CDC), 8.9 million adults aged 20 years old or older had diabetes and approximately half of these were women ([CDC National Diabetes Statistics Report, 2014](#)) ([Table 10.1](#)). Another 86 million adults are expected to have prediabetes, a condition associated with an elevated risk of developing frank diabetes. The rapidly rising rate of diabetes parallels the rising rates of obesity and appears to be notable for a more prominent rise in type 2 diabetes (more typically associated with insulin resistance common with obesity) as compared with type 1 diabetes (characterized by insulin deficiency) ([Figs. 10.1–10.2](#)). The rise in type 2 diabetes diagnoses is noted in adults as well as in children and adolescents ([Dabelea et al., 2014](#)). Similarly, there has been a significant increase in the prevalence of gestational diabetes mellitus (GDM, elevated blood sugars due to insulin resistance arising for the first time in pregnancy); studies suggest that US prevalence rates more than doubled over a 15-year period ([Getahun et al., 2008](#)). Data from 2010 derived from birth certificates as well as the Pregnancy Risk Assessment Monitoring System estimated the prevalence of GDM in the United States to be as high as 9.2% ([DeSisto et al., 2014](#)). Increasing rates of GDM are hypothesized to be due to increasing rates of obesity, which is known risk factor ([Fig. 10.1](#)), older maternal ages at delivery, as well as physical inactivity, smoking, and diets high in saturated fats ([Ferrara, 2007](#)).

Given the statistics noted above, diabetes represents one of the most common medical disorders in pregnancy and can have profound implications on fetal and neonatal health and outcomes. There is good evidence that maternal pregestational diabetes is associated with an increased risk of congenital anomalies, abnormalities in fetal growth, as well as neonatal complications such as hypoglycemia, electrolyte abnormalities, respiratory distress, and cardiomyopathy. There is increasing evidence that the intrauterine environment in the context of maternal diabetes may impact pediatric neurodevelopmental outcomes as well as risks of chronic disorders such as obesity and the metabolic syndrome.

Types of Diabetes

Type 1 Diabetes

Type 1 diabetes is characterized by insulin deficiency resulting from autoimmune destruction of pancreatic insulin-producing beta cells. Historically, most women with type 1 diabetes will develop clinical signs and symptoms of diabetes in childhood. More recently, adult onset of autoimmune diabetes has also been recognized (latent autoimmune diabetes of adults). These women are dependent on exogenously administered insulin; their underlying pathophysiology places them at elevated risk for diabetic ketoacidosis (DKA), which may be particularly challenging in pregnancy.

Type 2 Diabetes

Type 2 diabetes is characterized by insulin resistance and is therefore more significantly associated with obesity. This form of diabetes is more prevalent in certain ethnicities: Latino, Native American, South Asian, and Pacific Islander populations have particularly high rates of type 2 diabetes. Although type 2 diabetes was historically of adult onset, there have been increasing rates of diagnoses of type 2 diabetes among children and adolescents that appear to parallel the rise in obesity rates in these age groups.

Monogenic Diabetes

Monogenic diabetes, which has also been referred to as maturity-onset diabetes of the young, accounts for approximately 1%–2% of all diabetes cases. Multiple types of monogenic diabetes exist; all of the genes involved share the common feature of affecting beta-cell development, function, or regulation. Clinical presentations

¹Significantly different from those aged 20–39.

²Significantly different from women of the same age group.

NOTES: Totals were age-adjusted by the direct method to the 2000 US census population using the age groups 20–39, 40–59, and 60 and over. Crude estimates are 36.5% for all, 34.5% for men, and 38.5% for women.

of monogenic diabetes are heterogeneous, with phenotypes varying according to the specific mutation. Most forms share the following clinical features: affected individuals are typically diagnosed before the age of 25 years and are not insulin dependent. Women with monogenic diabetes may be first identified and diagnosed with diabetes during pregnancy and then are found to have continued hyperglycemia postpartum; genetic testing may be prompted by the recognition of a strong family history of diabetes (often two or more consecutive affected generations), as well as an absence of obesity or other clinical features suggestive of insulin resistance.

The most commonly affected genes identified in cases of monogenic diabetes are glucokinase (*GCK*) and hepatocyte nuclear factor (*HNF1A*, *HNF4A*). Glucokinase catalyzes the first and

rate-limiting step in glycogen storage and glycolysis; this enzyme effectively links insulin secretion to elevations in serum glucose. Mutations that inactivate *GCK* raise the glucose setpoint for insulin secretion. Women with *GCK* mutations usually have a stable, mild hyperglycemia with elevated fasting glucose levels most prominent. *HNF* genes encode transcription factors that play an important role in pancreatic beta-cell differentiation, development, and function; mutations in these genes typically produce a progressive defect in insulin secretion that results from progressive beta-cell failure. *HNF* mutations represent the most common cause of monogenic diabetes in most reported series to date: in a series reporting on monogenic diabetes in the United Kingdom, mutations in *HNF1A* and *HNF4A* accounted for approximately 50% and 10% of monogenic diabetes, respectively (Naylor and Philipson, 2011). *HNF1A* mutations in particular appear to have high penetrance, with 63% of affected individuals developing diabetes by age 25 years and 79% developing diabetes by age 35 years (Murphy et al., 2008; Naylor and Philipson, 2011).

Monogenic diabetes has several clinically relevant implications in pregnancy. The specific form of monogenic diabetes may affect responsiveness to certain therapies. Women with diabetes due to *HNF1A* or *HNF4A* mutations appear to be significantly more responsive to sulfonylureas (e.g., glyburide) than to biguanides (metformin). Increased sensitivity to sulfonylureas in *HNF1A* mutation carriers may be explained by sulfonylurea action on beta-cell potassium channels that are located downstream from the defect produced by the mutation; therefore if oral hypoglycemic therapy is preferred for treatment during pregnancy, glyburide is expected to be a more effective choice than metformin. Given the pathophysiology of diabetes resulting from *GCK* mutations, hyperglycemia in pregnancy may be more difficult to treat; this has been observed in clinical series (Bacon et al., 2015).

The genetic mutations leading to monogenic diabetes are inherited in an autosomal dominant fashion, so there is a 50%

risk of inheritance in the offspring. Whether or not the fetus is affected by a particular gene mutation may impact intrauterine growth. Affected fetuses with *HNF4A* mutations may have a greater likelihood of macrosomia and neonatal hypoglycemia. In an analysis of siblings discordant for the *HNF4A* mutation, affected infants had birth weights that were on average 790 g higher than unaffected infants; 56% of affected infants were macrosomic (birth weight >4000 g), as compared with 13% of those who were unaffected. Fifteen percent of affected infants demonstrated evidence of neonatal hypoglycemia (Pearson et al., 2007). In contrast, fetuses who have inherited the *GCK* mutation do not appear to demonstrate the excessive fetal growth that typically results from maternal hyperglycemia; studies have reported that affected fetuses may have a birth weight that may be 500–600 g lower than unaffected fetuses of mothers with monogenic diabetes due to *GCK* mutations (Spyer et al., 2001; Spyer et al., 2009; Bacon et al., 2015). Fetuses inheriting the *GCK* mutation may not respond to maternal (and therefore fetal) hyperglycemia by significantly increasing insulin secretion; therefore they may not experience the same pathologic growth patterns in response to maternal diabetes. Unaffected fetuses have a normally functioning glucokinase enzyme and are therefore at risk for hyperinsulinemia in response to maternal hyperglycemia, resulting in a greater risk of macrosomia. Knowledge of the fetal genotype during pregnancy might theoretically allow providers and patients to tailor diabetes management (e.g., recommend tight glycemic control when fetuses are unaffected but consider more relaxed glycemic targets when fetuses are affected). Despite the possible appeal of such a management strategy, the invasive testing (chorionic villous sampling or amniocentesis) necessary to determine the fetal genotype is unlikely to be accepted by patients given the potential for procedure-associated complications (although low risk). Some experts have suggested considering use of serial ultrasound assessment of fetal abdominal circumference and/or growth to help tailor diabetes management. In a general GDM population, maternal diabetes therapy guided by capillary blood glucose measurements versus a strategy of determining glycemic targets based on fetal abdominal circumference (high-risk abdominal circumference defined as ≥ 70 –75th percentiles for gestational age [GA]) appeared to perform comparably in terms of rates of macrosomia and neonatal morbidity (Kjos et al., 2001, 2007).

The management of diabetes during pregnancy may also have long-term effects on fetuses who inherit diabetes-causing mutations. Studies have demonstrated that individuals who inherit *HNF1A* mutations from their mothers often have earlier age at diabetes diagnosis and at initiation of insulin therapy than those who inherited their mutation from their fathers (Colom and Corcoy, 2010); this observation may suggest that the intrauterine environment can impact the phenotype produced by these mutations and further highlights the importance of good maternal metabolic control during pregnancy in optimizing long-term outcomes in her offspring.

Gestational Diabetes

Historically, the reported incidence of diabetes in pregnancy ranges from 6%–7%; 80%–90% of these cases are due to GDM, which is defined by the presence of elevated blood sugars, resulting from insulin resistance arising for the first time during pregnancy. It is likely that physiologic changes of pregnancy produce these elevated blood sugars in women with an underlying predisposition. In pregnancy, insulin resistance increases with advancing gestation in response to increasing levels of human placental lactogen, progesterone, cortisol, and prolactin. Human placental lactogen and

• BOX 10.1 Criteria for the Diagnosis of Diabetes (American Diabetes Association)

Clinical signs and symptoms of hyperglycemia – e.g., polyuria, polydipsia
Hemoglobin A_{1c} $\geq 6.5\%$
Fasting plasma glucose ≥ 126 mg/dL
Random plasma glucose ≥ 200 mg/dL
75-g, 2-hour oral glucose tolerance test with 2-hour value ≥ 200 mg/dL

prolactin antagonize the effects of insulin at the cellular level. Progesterone decreases gastrointestinal motility, which may enhance carbohydrate absorption. To a certain extent, insulin resistance in pregnancy is likely a physiologic adaptation as it helps to maintain a steady supply of nutrients to the growing fetus.

Given the underlying pathophysiology of insulin resistance, there is likely to be some overlap between women with type 2 diabetes and women diagnosed with GDM. Because of the likelihood that underlying type 2 diabetes may be first diagnosed in pregnancy (and therefore mistaken for GDM), it is recommended that women with risk factors for type 2 diabetes be screened early in pregnancy (Box 10.1). Risk factors that merit early diabetes testing include the following: a previous history of GDM; history of impaired glucose tolerance; and obesity (body mass index [BMI] ≥ 30 kg/m²). The American Diabetes Association also recommends consideration of testing for diabetes in women who are overweight (BMI 25–29 kg/m²) and who have one of the following additional risk factors: physical inactivity, a first-degree relative with diabetes, history of delivery of a macrosomic infant (defined as birth weight greater than 9 lbs), having an ethnic background associated with elevated risk of diabetes (African-American, Latina, Native American, Asian-American, or Pacific Islander), or having a history of polycystic ovarian syndrome or chronic hypertension. Women who have negative early screens for diabetes should be retested for GDM later in pregnancy. Universal testing for GDM at 24–28 weeks' gestation is recommended.

Currently in most of the United States, two-step testing is recommended with a 50-g glucose challenge test as the initial screen, followed by definitive diagnostic testing with a 100-g 3-hour oral glucose tolerance test; this testing approach is endorsed by the American College of Obstetricians and Gynecologists (ACOG). The International Association of Diabetes and Pregnancy Study Groups (IADPSG) recommends a one-step testing strategy utilizing a 75-g 2-hour oral glucose tolerance test. The IADPSG selected diagnostic thresholds for this test based on blood glucose levels that were associated with an odds ratio of 1.75 for various adverse outcomes evaluated in the Hyperglycemia and Adverse Pregnancy Outcome study (Metzger et al., 2010). It has been estimated that use of the IADPSG testing strategy would significantly increase the diagnosis of GDM (as many as 18% of pregnant American women may be diagnosed with GDM). The clinical benefits and cost-effectiveness of using the IADPSG testing recommendations require continued study (NICHD Consensus Development Conference panel, 2013).

Diabetic Embryopathy

In women with pregestational diabetes, poor periconceptional glycemic control has been associated with a significantly increased risk of embryopathy resulting in congenital malformations. The background rate of congenital malformations in the general population is around 2%–3%; in women with pregestational diabetes

the reported incidence of major congenital anomalies is approximately threefold higher at 6%–9%. The risk of congenital malformations increases with increasing maternal periconception hemoglobin A_{1c} (HbA_{1c}); women with a first trimester HbA_{1c} greater than or equal to 7.5% had a ninefold increased risk of congenital malformation than those women with good glycemic control (Miller et al., 1981; Temple et al., 2002; Nielsen et al., 2006). Extremely elevated maternal HbA_{1c} levels (i.e., ≥10%) in early pregnancy are associated with fetal malformation rates of 20%–25% (Greene, et al., 1989; Kitzmiller et al., 1996). Notably, the increased risk of fetal malformations in offspring of diabetic women reflects an increased risk of both major and minor congenital malformations. In studies evaluating the risk of diabetic fetopathy, major congenital malformations were often defined as any malformation anticipated to be lethal, likely to cause serious future handicap, or require surgical repair.

In a Finnish prospective cohort study of 709 offspring born to 488 women with type 1 diabetes, poor glycemic control in the first trimester (HbA_{1c} ≥9.4% at GAs <14 weeks) was associated with a sixfold increased relative risk (RR) of major fetal malformation (8.2% vs 1.4% in offspring of nondiabetic control patients) (Suhonen et al., 2000). In a Danish prospective cohort study of 933 singleton pregnancies in women with type 1 diabetes, 10.9% of the offspring to women with periconceptional HbA_{1c} greater than or equal to 10.4% had a major congenital malformation as compared with only 2.8% of the background population (Jensen et al., 2009).

Preconception care emphasizing the importance of good glycemic control before and during early pregnancy has been demonstrated to be associated with lower rates of congenital anomalies (Ray et al., 2001); achievement and maintenance of HbA_{1c} levels in the normal range (e.g., ≤6%) periconceptionally appears to confer a risk of congenital malformations that does not differ from the background population risk.

There is no anomaly that is pathognomonic for maternal diabetes. A wide range of congenital malformations affecting multiple organ systems have been reported in pregnancies complicated by pregestational diabetes. Pregestational diabetes confers a 26-fold increase in odds of caudal regression syndrome, but a large retrospective cohort study demonstrated that only 17% of all caudal regression cases occurred in women with diabetes (Garne et al., 2012). The most frequently encountered anomalies in the setting of maternal diabetes affect the cardiovascular system (3.5 times increase in odds in women with diabetes as compared to the background population) as well as the CNS (Table 10.2). Multiple congenital anomalies have been identified in 8%–13% of infants of diabetic mothers (IDMs) (Eidem et al., 2010; Garne et al., 2012).

High levels of glucose and ketone bodies (e.g., β-hydroxybutyrate) have been shown to be teratogenic in animal models. Hyperglycemia leads to the increased production of reactive oxygen species, which can alter cell membranes, cause mitochondrial dysfunction, or promote pathologic apoptosis; all of these alterations can contribute to embryopathy (Ornoy et al., 2015). Animal studies have demonstrated that hyperglycemia-induced excessive apoptosis affects neural progenitor cells, contributing to nervous system malformations (Yang et al., 2015). Hyperglycemia-related oxidative stress has also been shown to have a direct effect on the proliferation and migration of neural crest cells, which play a critical role in the development of the fetal heart; in animal models, these changes resulted in cardiac outflow tract defects (Morgan et al., 2008).

Congenital malformation risk in pregestational diabetics may be further increased by exposure to medications that may be teratogenic. Women with diabetes have a greater risk of comorbid medical

TABLE 10.2 Congenital Anomalies Reported in Fetuses of Diabetic Mothers

| Organ System | Anomalies |
|-------------------------------|--|
| Central nervous system | Spina bifida Anencephaly Hydrocephalus |
| Cardiovascular system | Ventricular septal defect Tetralogy of Fallot Transposition of the great arteries Hypoplastic left heart syndrome Coarctation of the aorta Atrial septal defect Pulmonic stenosis Double-outlet right ventricle Truncus arteriosus |
| Genitourinary tract | Hydronephrosis Renal agenesis Ureteral duplication Hypospadias |
| Gastrointestinal tract | Intestinal atresias Anal atresia |

conditions such as chronic hypertension or complications of long-standing diabetes (e.g., nephropathy). In this setting, angiotensin-converting enzyme (ACE) inhibitors may be prescribed outside of pregnancy; these medications are known to be teratogenic: in a nondiabetic population, first trimester exposure has been associated with a 2.7-fold increased risk of major congenital malformations, including a fourfold increase in the risk of CNS anomalies and a 3.7-fold increase in the risk of cardiovascular anomalies (Cooper et al., 2006). Exposure to ACE inhibitors beyond the first trimester of pregnancy also has adverse effects, including fetal renal failure, oligohydramnios with its associated consequences (e.g., pulmonary hypoplasia if early oligohydramnios is severe and persistent), fetal growth restriction, and increased risk of stillbirth.

Antenatal detection of congenital malformations usually requires targeted second trimester ultrasound evaluation. Systematic reviews evaluating the accuracy of ultrasound diagnosis at GAs less than 24 weeks report detection rates of 16%–44% for all anomalies (Grandjean et al., 1999; Whitworth et al., 2010); the overall detection rate of major lethal anomalies is higher, at 84% (Reddy et al., 2014). Detection rates differ based on the type of malformation – detection rates are higher for major malformations such as anencephaly and spina bifida than for more subtle malformations such as unilateral renal agenesis or small ventricular septal defects. Rates of detection also likely vary based on GA at the time of ultrasound exam, expertise of the sonographer, and patient factors (e.g., maternal obesity).

Cardiac anomalies comprise up to 40%–50% of congenital malformations encountered in IDMs; it is estimated that there is a fivefold increase in risk of congenital cardiac anomalies in IDMs as compared with infants of women without diabetes (Rowland et al., 1973; Wren et al., 2003). In a case-control study of around 8000 live and stillborn infants weighing greater than or equal to 500 g and greater than or equal to 20 weeks' gestation, the absolute risk of a major cardiovascular system defect was 8.5 per 100 live births in offspring of insulin-dependent diabetic mothers; in that population, the absolute risk of a cardiovascular malformation in

infants born to nondiabetic mothers was 0.8 per 100 live births (Becerra et al., 1990).

Given the increased risk of morbidity and mortality with some cardiac malformations, antenatal diagnosis is vital for optimization of obstetric and neonatal care. Some studies have suggested that antenatal diagnosis of complex cardiac malformations such as hypoplastic left heart syndrome or transposition of the great arteries may be associated with an improvement in neonatal outcomes as compared with infants in whom these malformations were first diagnosed postnatally. Routine second trimester fetal ultrasound evaluation of the basic cardiac views (four-chamber and outflow tract views) has a sensitivity of 60%–85%. Fetal echocardiography has been shown to have an increased sensitivity of 85%–95%, with positive predictive value of 90% and negative predictive value of 93% for the diagnosis of many types of cardiac malformations (Bakiler et al., 2007). Given the increased risk of cardiac malformations in fetuses of diabetic women, many American institutions recommend screening fetal echocardiography in addition to a detailed second trimester fetal anatomic survey.

Fetal Growth and Macrosomia

Maternal diabetes is associated with an increased risk for abnormal fetal growth. Pregestational diabetics with microvascular complications (especially diabetic nephropathy) or concomitant chronic hypertension may have an increased risk of intrauterine growth restriction, which may be related to abnormalities in placental structure or perfusion.

Excessive fetal growth is the aberrant pattern more commonly encountered in diabetic pregnancies. Large for gestational age (LGA) is commonly defined as birth weight greater than the 90th percentile for GA. Macrosomia is more variably defined: birth weight greater than 4000 g or greater than 4500 g without adjustment for GA. Both pregestational and gestational diabetic pregnancies have a greater prevalence of LGA and macrosomic infants: LGA has been reported to occur in 25%–42% pregestational diabetics (Jovanovic-Peterson et al., 1991). Birth weights greater than or equal to the 90th percentile have been reported to occur in 42%–62% of type 1 diabetic pregnancies, 30%–56% of type 2 diabetic pregnancies, and in 10%–20% of pregnancies complicated by gestational diabetes. For infants born to nondiabetic mothers, the rate of macrosomia (when defined as birth weight ≥ 4000 g) has been reported to be 7%–8% (Langer et al., 1991), and the rates of LGA have been reported to be 8%–14% (Jovanovic-Peterson et al., 1991).

Excessive fetal growth is probably stimulated by maternal hyperglycemia as explained in the classic Pedersen hypothesis. Maternal glucose readily crosses the placenta by facilitated diffusion; fetal glucose levels are maintained at a level that is approximately 70%–80% of the maternal concentration of glucose. Maternal insulin does not cross the placenta. Fetal hyperglycemia stimulates fetal pancreatic beta-cell hypertrophy and increased insulin production. Insulin acts as a potent growth factor in utero – fetal hyperinsulinemia and concomitant increases in insulin-like growth factors (IGFs) probably results in increased protein, lipid, and glycogen synthesis that contributes to increased fetal growth (Langer, 2000). The excess fetal growth seen in IDMs appears to be characterized by increased fat deposition as well as observation of visceral enlargement. Fetal insulin activity in response to fetal glucose levels becomes evident at around 20 weeks' gestation. Insulin receptor levels in target organs such as the fetal liver appear to become maximal in the mid-trimester, with insulin receptor binding affinities increasing as pregnancy progresses.

Maternal glycemic control has been identified as a predictor of abnormal fetal growth. Studies have demonstrated a positive linear association between maternal glucose levels and risk of LGA birth weights (HAPO Study Cooperative Research Group, 2008). Elevated maternal HbA_{1c} levels and nonfasting as well as mean glucose levels have been associated with risk of abnormal fetal growth (Jovanovic-Peterson et al., 1991; Gandhi et al., 2008). Clinical studies have also demonstrated a positive correlation between fetal insulin and IGF levels and birth weight. Amniotic fluid insulin levels have been shown to correlate with risk of macrosomia as well as childhood obesity (Metzger et al., 1990; Carpenter et al., 2001). Demonstrated a significant increase in fetal cord blood IGF-I levels in the late third trimester (34 weeks through term); these fetal IGF-I levels correlated positively with newborn weights in their cohort of nondiabetic women.

The clinical pattern of abnormal fetal growth in the context of maternal diabetes appears to be characterized by accelerated disproportionate growth in the second half of pregnancy. Studies evaluating fetal growth utilizing ultrasound assessment demonstrated that LGA IDMs had evidence of accelerated growth as early as 17–24 weeks' gestation, with maximal growth occurring late in the third trimester. Observations of accelerated fetal abdominal circumference growth have been made in diabetic pregnancies and associated with LGA birth weights (Greco et al., 2003; Mulder et al., 2010; Hammoud et al., 2013). LGA IDMs have evidence of increased adiposity when compared with LGA infants born to nondiabetic women. In an evaluation of LGA neonates, IDMs had significantly increased fat mass and increased percentage body fat as compared with infants whose mothers had normal gestational glucose tolerance (Durnwald et al., 2004). In general, fetal fat deposition seems to occur almost entirely within the third trimester and appears to be very sensitive to the effects of fetal insulin.

Antenatal diagnosis of macrosomia has been made difficult by limitations in the accuracy of fetal sonographic estimations of fetal weight. Measurements of the fetal head (head circumference and biparietal diameter), abdominal circumference, and femur length are incorporated into a formula (usually derived from nonlinear regression analysis) to estimate fetal weight; fetal weight percentiles are then determined from one of several fetal growth curves that, historically, have been derived from various geographic locations using representative subpopulations. Most experts consider a mean percent error in estimated fetal weight of $\pm 10\%$ to be clinically relevant for accuracy. Studies evaluating the accuracy of third-trimester ultrasound estimates of fetal weight show that sonographic estimates fall within 10% of birth weight in 50%–75% of cases; the reported mean percentage differences between ultrasound-predicted and actual birth weight have ranged from 6%–15% (Schwartz et al., 2016).

Sensitivities for the antenatal diagnosis or prediction of birth weight greater than or equal to 4000 g has been estimated to be as low as 53%–59% (Porter et al., 2015). In a cohort of women with gestational diabetes, third-trimester ultrasound estimation of fetal weight significantly overestimated the prevalence of LGA infants; of those women identified as having an estimated fetal weight greater than or equal to the 90th percentile, only 23% actually delivered an LGA neonate (Scifres et al., 2015). Some data suggest that prediction of clinically relevant LGA (e.g., LGA infants who will have the greatest risk of shoulder dystocia) may be improved by the use of customized fetal growth curves, which take into account clinical factors such as fetal gender, maternal height, weight, parity, and ethnicity that are physiologic determinants of fetal growth (Larkin et al., 2011).

Macrosomic IDMs have a greater risk of shoulder dystocia, birth trauma (including perinatal acidosis), cesarean delivery, and of neonatal complications such as severe hypoglycemia and hyperbilirubinemia (Ballard et al., 1993). Shoulder dystocia is defined as difficulty and delay in delivery of the fetal shoulders/body following delivery of the fetal head; this often results from impaction of the anterior fetal shoulder behind the maternal pubic bone. Shoulder dystocia requires additional obstetric maneuvers to effect delivery; typical management includes McRoberts maneuver, which produces hyperflexion of the maternal hips to widen the pelvic outlet, suprapubic pressure to attempt to dislodge the impacted anterior fetal shoulder, and/or delivery of the fetal posterior arm.

Shoulder dystocia represents an obstetric emergency as delayed delivery is associated with an increased risk of perinatal asphyxia (potentially related to impaired oxygenation from occlusion of the umbilical cord during delayed delivery). Both the condition of shoulder dystocia and the obstetric maneuvers required to effect delivery may lead to an increased risk of birth trauma, including brachial plexus injuries and clavicular or humeral fractures. In a general obstetric population, reported rates of shoulder dystocia range from 0.2%–3%. Macrosomia and maternal diabetes have been identified as independent risk factors for shoulder dystocia. In a nondiabetic population, macrosomia, when defined as birth weight greater than 4500 g, was associated with a 13-fold increase in the odds of shoulder dystocia as compared with non-macrosomic infants; the rate of shoulder dystocia in a nondiabetic population with macrosomic infants was 23% (Froehlich et al., 2016). When controlling for birth weight and other confounders, diabetes (pregestational and gestational) is an independent risk factor for shoulder dystocia, with a threefold increase in odds (Nesbitt et al., 1998). Women with the highest risk for shoulder dystocia are diabetics with a macrosomic infant; shoulder dystocia rates as high as 35% have been reported in diabetic women who deliver an infant with a birth weight between 4750 and 5000 g (Young and Ecker, 2013). In deliveries complicated by shoulder dystocia, IDMs have a greater rate of birth trauma than infants of nondiabetic mothers; in a review of shoulder dystocia cases in the state of California, 24% of IDMs and 7.3% of infants of nondiabetic mothers had evidence of birth trauma (Nesbitt et al., 1998).

Birth trauma appears to occur at an increased rate in macrosomic infants even in the absence of shoulder dystocia. In a cohort of infants with a birth weight greater than or equal to 4000 g, 7% had evidence of a traumatic birth injury – most commonly Erb's palsy and clavicular or humeral fractures (Cordero et al., 1998). Macrosomic infants also have an increased risk of requiring cesarean delivery; cesarean delivery rates as high as 50%–60% for infants with birth weights greater than or equal to 4000 g have been reported (Cordero et al., 1998).

Stillbirth and Perinatal Mortality

Pregnancies complicated by diabetes have been noted to have an increased risk of stillbirth (usually defined as fetal demise diagnosed at GAs at or beyond 20 weeks) as well as perinatal mortality. Perinatal mortality has varying definitions; the most inclusive definition is a fetal death at 20 weeks or more or an infant death before 28 days of life (Mathieson et al., 2011). The most recent US National Vital Statistics Report from 2013 demonstrated a fetal death (stillbirth) rate of 5.96 per 1000 live births. The perinatal mortality rate was 9.98 per 1000 live births plus fetal deaths for the time period of evaluation (MacDorman and Gregory, 2015).

This report did not specify fetal death rates or perinatal mortality rates for pregnancies complicated by specific medical or obstetric comorbidities. Studies evaluating the risk of perinatal mortality in pregnancies complicated by diabetes may have been limited by variable definitions of perinatal mortality as well as a lack of uniform agreement regarding how to determine if maternal diabetes was a direct contributor to the demise.

The stillbirth risk among women with pregestational diabetes has been reported to be as high as five times the risk of stillbirth noted in the general population (Casson et al., 1997; Wood et al., 2003). In the United States, a multicenter population-based case-control study identified maternal diabetes as an independent risk factor for stillbirth, accounting for 5.6% of all stillbirths in the cohort (for stillbirths occurring at GAs of ≥ 24 weeks, the adjusted odds ratio of stillbirth in women with diabetes was 3.47, 95% confidence interval [CI] 1.86–6.49) (Stillbirth Collaborative Research Network Writing Group, 2011).

The reported risk of stillbirth may differ in women with type 1 diabetes as compared with those with type 2 diabetes. In large Danish cohort studies, incidences of stillbirth among women with type 1 diabetes ranged from 18–28 per 1000 births as compared with a rate of 4.5 per 1000 births in the general population (Lauenborg et al., 2003; Jensen et al., 2004). The risk of stillbirth is similarly elevated in women with type 2 diabetes, although the magnitude of risk that has been reported has varied, with some studies suggesting worse outcomes in type 2 diabetes while others suggest comparable outcomes in both type 1 and type 2 diabetes. Large retrospective cohort studies conducted in Denmark and in New Zealand demonstrated perinatal mortality rates two to three times higher in women with type 2 diabetes as compared with those who have type 1 diabetes (Cundy et al., 2000; Clausen et al., 2005). It is possible that the risk of perinatal mortality may be increased in pregnancies complicated by type 2 diabetes because these women have an increased risk of obesity. Obesity has been shown to be an independent risk factor for adverse pregnancy outcomes, including stillbirth and gestational hypertensive disorders, which can also impact fetal growth and risks of prematurity (O'Brien et al., 2003; Athukorala et al., 2010; Aune et al., 2014; Yao et al., 2014). A systematic review evaluating population-based studies reporting on risk factors for stillbirth in high-income countries (such as the United States, Canada, the United Kingdom, Australia, and the Netherlands) demonstrated that diabetes is a maternal medical comorbidity with one of the strongest associations with stillbirth. In this systematic review, women with preexisting diabetes had an adjusted odds of stillbirth 2.9 times that of women without diabetes; however, the calculated population-attributable risk of diabetes to stillbirths is 3%–5%. In comparison to diabetes, maternal overweight and obesity (defined as maternal BMI >25 kg/m²) had a higher population-attributable risk for stillbirth (8%–18%). Maternal overweight and obesity were identified as the highest ranking modifiable risk factor for stillbirth in high-income countries (Flenady et al., 2011).

The risk of perinatal mortality in pregnancies complicated by GDM is not clear: several studies have suggested an increased risk of perinatal mortality with GDM, while other studies have not demonstrated a significant association. Some women with GDM are likely to be type 2 diabetics who just happen to be identified during pregnancy; therefore the possibility of misclassification might explain the discrepancy in reported results. A large retrospective cohort study evaluating outcomes of singletons delivered in California at 36–42 weeks' gestation demonstrated that there was an increased risk of stillbirth in women with GDM as compared with

women without diabetes, though the absolute risks are low: women with GDM experienced 17.1 stillbirths per 10,000 deliveries, whereas nondiabetic women had 12.7 stillbirths per 10,000 deliveries (RR 1.34, 95% CI 1.2–1.5). This same study also evaluated the risk of expectant management in pregnancies complicated by GDM and concluded that at 39 weeks' gestation, the risk of expectant management (stillbirth and infant mortality risks) appears to exceed the risks of delivery (Rosenstein et al., 2012). Results from similar studies inform recommendations for consideration of delivery at 39–40 weeks' gestation in pregnancies complicated by GDM requiring medical therapy. Women with diet-controlled GDM have not been shown to have greater risk of stillbirth (Karmon et al., 2009), and their delivery planning is managed accordingly.

Several studies evaluating risks of adverse outcomes in the setting of maternal diabetes have identified an association between poor glycemic control and increased risk of perinatal mortality. The etiologies of perinatal mortality that may be relevant in pregnancies complicated by diabetes include severe congenital malformations, growth abnormalities (e.g., fetal growth restriction in women with microvascular complications of diabetes), prematurity, and intrauterine asphyxia (Dudley, 2007). Each of these etiologies is anticipated to occur with increased frequency in the setting of poor maternal glycemic control and severity of diabetes. Poorly controlled diabetes early in pregnancy may contribute to abnormalities in placental development: high glucose levels have been shown to have an inhibitory effect on human trophoblast invasion (Belkacemi et al., 2005). Placental pathology of this nature might be hypothesized to impact placental function and therefore impact risk of intrauterine demise.

Intrauterine asphyxia may result from fetal hyperinsulinemia that is thought to increase fetal oxygen consumption and therefore decrease fetal oxygen tension; this proposed pathophysiology seems supported by the observation that some fetuses of women with type 1 diabetes have higher plasma lactate levels and lower blood pH levels than normal when evaluated by third-trimester cordocentesis (Bradley et al., 1991). This lactic acidemia observed in some of the fetuses of diabetic women may contribute to the risk of perinatal mortality.

One etiology of fetal death that is unique to diabetes is maternal DKA. Pregnancy represents a time of increased risk of DKA as several of the physiologic changes of pregnancy predispose to DKA. Pregnancy results in increased insulin resistance, enhanced lipolysis, and ketogenesis. Pregnant women are also in a state of compensated respiratory alkalosis; therefore there is decreased buffering capacity (lower plasma bicarbonate levels) in the setting of acidosis. Complications unique to pregnancy such as nausea and vomiting further increase risk of DKA.

The perinatal mortality rate in the setting of maternal DKA has been reported to be 9%–35%. The exact mechanism of fetal death in the setting of maternal DKA is not completely understood. It is known that maternal ketone bodies freely cross the placenta and contribute to fetal acidosis. Maternal DKA is also characterized by significant maternal hypovolemia (resulting from osmotic diuresis), which likely results in decreased uteroplacental perfusion. Maternal acidemia also shifts the maternal oxyhemoglobin dissociation curve leftward, thus further compromising oxygen delivery to the fetus. Decreased fetal oxygenation and metabolic acidemia are likely significant contributors to fetal mortality in this setting. Women who develop DKA during pregnancy are often critically ill; as expected, fetal status often reflects maternal illness. Fetuses often demonstrate evidence of intrauterine distress during fetal heart

rate monitoring. In this setting, obstetric management prioritizes maternal stabilization; emergent cesarean delivery for fetal distress resulting from DKA before adequate maternal treatment and stabilization is associated with high risk of maternal morbidity and mortality. Fortunately, early recognition of maternal DKA and aggressive, efficient initiation of treatment can lead to maternal improvement and effective intrauterine resuscitation of the fetus.

Prevention of perinatal mortality in pregnancies complicated by diabetes primarily relies on ensuring good maternal glycemic control throughout gestation. Increased antenatal surveillance to try to identify at-risk fetuses is also an accepted part of the obstetric management of pregestational diabetic women. Given the conflicting data regarding risks of perinatal mortality in women with GDM, current expert guidelines recommend antenatal testing for women with GDM who require medication therapy for hyperglycemia at the same time suggesting that testing may be deferred in women with GDM who are well controlled on dietary therapy alone and who are otherwise at low risk for perinatal complications.

Maternal Preeclampsia

Preeclampsia is a gestational hypertensive disorder; the diagnosis of preeclampsia is made with the onset after 20 weeks' gestation of persistent elevations in systolic blood pressure (≥ 140 mmHg) or diastolic blood pressure (≥ 90 mmHg) in women with previously normal blood pressure as well as the new onset of proteinuria. Proteinuria is defined as greater than or equal to 300 mg of protein per 24-hour urine collection or a protein/creatinine ratio greater than or equal to 0.3. The diagnosis of preeclampsia may also be made in the absence of proteinuria if there are other complications such as thrombocytopenia, renal insufficiency, impaired liver function, pulmonary edema, or neurologic symptoms (such as cerebral or visual symptoms) or HELLP syndrome (ACOG Task Force on Hypertension in Pregnancy, 2013). In addition to the aforementioned maternal complications, preeclampsia is also associated with an increased risk of fetal complications such as intrauterine growth restriction and oligohydramnios that are likely to reflect altered placental perfusion in the setting of preeclampsia. Women with severe forms of preeclampsia are also at increased risk of placental abruption. Delivery is the only definitive treatment for preeclampsia. In the setting of maternal or fetal complications resulting from preeclampsia, delivery is medically indicated as the risk of perinatal and maternal morbidity and mortality is elevated (Clark et al., 2008; Kuklina et al., 2009).

Women with pregestational diabetes are at increased risk for developing preeclampsia. The prevalence of preeclampsia in the general population has been estimated at 4.6% (Abalos et al., 2013), and the frequency of preeclampsia in women with diabetes has been reported to be 2–4 times higher than the general population. Among women with diabetes, the risk of preeclampsia appears to increase with increasing duration of diabetes as well as with the presence of microvascular complications. In a US prospective observational cohort study, 11% of women with a duration of diabetes of less than 10 years developed preeclampsia as compared with 22% of women with diabetes of duration 10–19 years. Thirty-six percent of women with proliferative diabetic retinopathy and/or diabetic nephropathy developed preeclampsia in this cohort. The women with diabetic nephropathy with a baseline level of proteinuria of greater than or equal to 300 mg in a 24-hour urine collection had an increased risk of small for GA infants and of preterm delivery (Sibai et al., 2000).

Obstetric Management of Diabetes in Pregnancy

Preconception Care

Care of the pregestational diabetic woman should ideally begin before pregnancy. As discussed previously, preconception care of a woman with diabetes can improve outcomes; if good glycemic control is achieved and maintained throughout conception and early pregnancy, rates of miscarriage and congenital malformations are often indistinguishable from the general population in women with uncomplicated diabetes (*The Diabetes Control and Complications Trial Research Group, 1996*). Preconception care also allows for identification of teratogenic medications and hopefully substitution with safer alternatives (e.g., discontinuation of ACE inhibitors and transition to other antihypertensives that are compatible with pregnancy). Given the elevated risk of neural tube defects in diabetic pregnancies, folic acid supplementation should be initiated before conception. Identification of microvascular complications of diabetes such as retinopathy and nephropathy before pregnancy allows opportunities for treatment of these conditions (e.g., laser therapy for treatment of cases of proliferative retinopathy); optimization of these conditions will hopefully prevent progression of disease during pregnancy. Women with microvascular complications of diabetes also appear to have an additional increased risk of adverse pregnancy outcomes; for example, women with diabetic nephropathy have an increased risk of having a fetus who develops intrauterine growth restriction and also have a risk of gestational hypertensive disorders such as preeclampsia that exceeds the risk conferred by diabetes alone. Low-dose aspirin has been evaluated as a possible intervention to reduce the risk of preeclampsia in women who have an a priori elevated risk of developing this obstetric complication, and its use has been found to confer a modest reduction in the risk of developing preeclampsia. Low-dose aspirin in pregnancy appears to have a good safety profile. The US Preventive Services Task Force has recommended the use of low-dose aspirin in women at elevated risk of developing preeclampsia including women with pregestational diabetes (type 1 or type 2) (*Henderson et al., 2014; LeFevre, 2014*).

Identification of women who have additional risk factors for adverse pregnancy outcomes may allow for pregestational optimization of medical comorbidities as well as closer maternal and fetal monitoring during pregnancy.

Medical Therapy for Diabetes in Pregnancy

In general, maintaining good glycemic control is a primary goal of the management of diabetes in pregnancy. The ideal target range for maternal blood glucose in pregnancy is not clear, though it is well established that average maternal blood glucose must be maintained at a much lower level than what is considered acceptable in the nonpregnant setting because fetal and neonatal complications occur with increased frequency even when maternal glucose levels are modestly elevated. Currently, expert consensus recommendations indicate the following targets for glycemic control in women with gestational diabetes: fasting capillary blood glucose (CBG) of less than 95 mg/dL, 1-hour postprandial CBG levels below 140 mg/dL, or 2-hour postprandial levels less than 120 mg/dL; pharmacologic therapy is strongly recommended for women whose CBGs exceed these thresholds (*ACOG, 2013*). In women with pregestational diabetes, expert consensus recommends the following goals: fasting CBG less than or equal to 90 mg/dL, 1-hour postprandial

CBG less than or equal to 130–140, or 2-hour postprandial levels less than or equal to 120 mg/dL (*ADA 2016 Standard of Medical Care in Diabetes*).

Results from the Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study raise the question of whether stricter glucose levels should be targeted. The HAPO study was a prospective multinational study that evaluated the relationship between maternal hyperglycemia and adverse pregnancy outcomes that has been attributed to maternal diabetes. The relationship between results from a 2-hour, 75-g oral glucose tolerance test and the following primary outcomes were evaluated: birth weight greater than the 90th percentile for GA; cord blood C-peptide levels greater than the 90th percentile; primary cesarean delivery; and clinical neonatal hypoglycemia. Maternal glucose values at each time point (fasting, 1 hour, and 2 hours after glucose challenge) were positively associated with the primary outcomes in a linear fashion. There was no apparent threshold glucose level above which risk for an adverse outcome was clearly elevated; frequencies of adverse outcomes rose steadily with worsening maternal hyperglycemia (*HAPO Study Cooperative Research Group, 2008*).

As many adverse fetal/neonatal outcomes such as macrosomia and neonatal hypoglycemia are thought to result from fetal hyperinsulinemia in response to maternal hyperglycemia, it may be relevant to consider the maternal blood glucose levels in women without diabetes. A review of 12 studies evaluating the glycemic profile of nondiabetic women demonstrated fasting glucose levels of 71 ± 8 mg/dL (mean \pm 1 standard deviation); 1-hour postprandial levels of 109 ± 122 mg/dL; and 2-hour postprandial levels of 99 ± 109 mg/dL. These results suggest that further clinical study of maternal goals for glycemic control is warranted.

Maintaining maternal glycemic control is made more difficult by physiologic changes of pregnancy that lead to worsening insulin resistance with advancing GA. Increasing levels of human placental lactogen and changes in levels of cortisol and prolactin are likely to exacerbate insulin resistance. Insulin sensitivity has been demonstrated to decrease by as much as 56% by 36 weeks' gestation. For women with pregestational diabetes, third-trimester insulin requirements may be two to three times greater than prepregnancy doses. Obese women with type 2 diabetes may demonstrate extreme levels of insulin resistance.

All women with diabetes require dietary therapy during pregnancy. Consultation with a registered dietician is an important part of care to ensure that the nutritional requirements of pregnancy are met and the distribution of calories from carbohydrates, proteins, and fats contributes to optimal glycemic control. In obese women, in particular, attention to dietary therapy is also critical to the goal of preventing excessive weight gain. Excessive weight gain appears to be an independent contributor to some adverse outcomes such as fetal macrosomia.

Medical management of maternal hyperglycemia in women with pregestational diabetes commonly relies on subcutaneous insulin. Insulin does not cross the placenta so does not have a risk of adverse impact on fetal development. Insulin has been well-studied in pregnancy and has been shown to be effective in achieving good maternal glycemic control and in reducing the risk of adverse obstetric outcomes.

Women with GDM or mild type 2 diabetes may be treated with oral medications such as metformin or glyburide instead of insulin. The use of oral medications, especially for the treatment of GDM, has become increasingly popular following the publication of clinical trials that demonstrated the effectiveness of these medications. Metformin has long been used in type 2 diabetes; it acts primarily

by decreasing hepatic glucose production, decreasing intestinal absorption of glucose, and by improving insulin sensitivity in peripheral tissues. Metformin has a low risk of producing hypoglycemia. In a randomized clinical trial comparing metformin with insulin for the treatment of GDM, there was no significant difference in neonatal outcomes, including hypoglycemia, birth trauma, respiratory distress, or hyperbilirubinemia (Rowan et al., 2008). It was notable that 46% of women in the metformin group ultimately required insulin in order to maintain glycemic control; these women were more likely to be overweight and appeared to have had higher fasting glucose values at study entry. Metformin therapy had the additional benefit of being associated with significantly less maternal weight gain than insulin therapy alone. Metformin is known to cross the placenta, but neonatal outcomes in IDMs who were exposed to metformin in utero appear to be reassuring overall.

Glyburide has also become an increasingly popular treatment option for GDM. Glyburide acts on the pancreas to promote and increase insulin secretion. When compared with insulin therapy in GDM, glyburide has been reported to be equally effective in achieving glycemic goals (Langer, 2000). Glyburide is also known to cross the placenta; given the actions of this medication on the pancreas, concern has been raised about the potential metabolic implications of in utero exposure to glyburide. Metaanalyses evaluating studies of glyburide versus insulin have suggested an approximately twofold increase in risk of macrosomia and in neonatal hypoglycemia with glyburide therapy in GDM (Poolsup et al., 2014; Jiang et al., 2015; Balsells et al., 2015). Given the complex regulation of fetal growth, it is difficult to know the degree to which abnormal growth can be attributed to glyburide exposure. Further studies regarding the long-term consequences of in utero glyburide exposure are needed.

Antenatal Monitoring

As discussed previously, pregnancies complicated by diabetes are at increased risk for abnormal fetal growth as well as perinatal asphyxia and stillbirth. These complications warrant increased antenatal surveillance in the third trimester. Results of testing or changes in the pattern of testing may help to inform decisions regarding timing and mode of delivery.

Fetal acidemia may produce characteristic changes on biophysical tests. Tests currently utilized include maternal assessment of fetal movement, fetal heart rate testing (nonstress test or contraction stress test), and ultrasound biophysical profile testing.

Maternal assessment of fetal movement is a frequently recommended component of fetal monitoring programs. Studies have noted that decreased fetal movement may be perceived in the period preceding fetal death. There does not appear to be a superior method for evaluation of fetal movement: an example of a protocol that has been suggested includes counting distinct fetal movements and considering 10 movements within 2 hours reassuring (Moore et al., 1989).

Fetal heart rate testing relies on a mature and normally functioning fetal autonomic system; in this setting, baseline fetal heart rate should be between 120 and 160 beats per minute, with moderate variability, and accelerations that occur with fetal movement. The pattern described corresponds with fetal heart rate reactivity. Fetal heart rate testing as a method of screening for fetal compromise is probably of limited clinical utility at earlier GAs. In an uncompromised fetus, the likelihood of a nonreactive fetal heart rate test is greater at preterm GAs: between 24 and 28 weeks' gestation, 50% of fetal heart rate tests are nonreactive; between 28 and 32 weeks' gestation, 15% of tests are nonreactive. In order to avoid false-positive

results on fetal heart rate testing, most centers do not initiate these screening tests until 32–34 weeks unless there are indications for earlier testing (e.g., concern for fetal growth restriction, poorly controlled maternal diabetes, or hypertension etc.).

At any GA, fetal heart rate decelerations that are greater than 1 minute in duration or that are late in timing relative to a contraction are abnormal and are associated with an increased risk of perinatal complications including fetal death; therefore further evaluation and consideration of delivery may be indicated based on the clinical context of these findings.

Biophysical profile testing relies on sonographic evaluation of amniotic fluid volume (measurement of a single pocket of fluid of at least 2-cm depth), fetal movement, demonstration of fetal tone (by extension and flexion of a fetal limb or opening and closing of a hand), and fetal breathing movements. Each component of this examination is given a score of 0 if absent or 2 if present. If a fetal nonstress test is also performed, then a reactive test is given a score of 2 while a nonreactive test is given a score of 0. Biophysical profile scores of 8–10 are considered normal and reassuring. A score of 6 is considered equivocal and requires additional evaluation. A score of 4 or less is considered abnormal and requires intervention.

It is not clear that antenatal fetal testing as described above is useful in preventing stillbirth or perinatal asphyxia, but these tests may be clinically useful in providing reassurance that fetal status is stable so as to allow for continued expectant management until a favorable term GA is reached. If stillbirth within 1 week of testing is used as the primary outcome of interest for antenatal fetal testing, both fetal heart rate testing and biophysical profile testing appear to have high negative predictive values (>99%) for reactive nonstress tests and biophysical profile scores of 8–10. In diabetic pregnancies (especially if poorly controlled), more frequent testing may be warranted as the fetal testing strategies above may miss fetal compromise precipitated by acute maternal metabolic changes. The appropriate frequency of fetal testing in pregnancies complicated by diabetes has been difficult to establish. Twice-weekly testing is commonly recommended in most centers. This testing strategy has been evaluated in a large retrospective cohort that demonstrated an overall low stillbirth rate, with the observation that none of the stillbirths occurred within 4 days of the last antepartum test (Kjos et al., 1995).

Evaluation of fetal growth also contributes to the assessment of fetal status. As discussed previously, third-trimester evaluation of fetal growth is significantly limited by increasing inaccuracy of predicted fetal weights as gestation progresses. Despite these limitations, third-trimester ultrasound assessment of growth is commonly recommended, given the risk of pathologic growth in diabetic pregnancies. For women with microvascular complications of diabetes, concomitant chronic hypertension, and preeclampsia, fetal growth restriction may confer further elevated risk of perinatal morbidity and mortality, thus necessitating additional antenatal testing (e.g., fetal umbilical Doppler studies) to help inform obstetric management. While fetal macrosomia has been difficult to accurately diagnose antenatally, findings suggestive of predicted birth weight above 4500 g appear to be associated with an increased risk of shoulder dystocia. In this setting, it may be reasonable to consider cesarean delivery in an attempt to avoid shoulder dystocia and resultant birth trauma.

Delivery Planning

Women with diet-controlled gestational diabetes appear to have a low risk of perinatal complications; therefore early delivery is

not indicated, and expectant management is usually appropriate. For pregestational diabetics and gestational diabetics requiring medication management, timed early delivery has been considered in an attempt to reduce perinatal morbidity and mortality. Strategies of scheduled delivery at 38–39 weeks for women with GDM have been evaluated in clinical trials; results have suggested that while there may be some potential reduction in macrosomia or LGA with earlier delivery, there does not seem to be a significant reduction in shoulder dystocia, neonatal hypoglycemia, or perinatal death (Kjos et al., 1993; Witkop et al., 2009). Given recent evidence that suggests early term births (at 37–39 weeks) may be associated with differences in rates of neonatal complications (such as respiratory complications) as compared with deliveries at term (39–40 weeks), it is probably reasonable for most well-controlled pregestational and gestational diabetics to plan for a delivery at around 39 weeks' gestation. Delivery at GAs greater than 40 weeks' gestation may be associated with a greater risk of macrosomia and shoulder dystocia (Lurie et al., 1996) and does not appear to be associated with other improvement in neonatal or maternal outcome. Elective cesarean delivery in fetuses suspected of macrosomia has also been considered. As discussed previously, macrosomic infants have a greater risk of shoulder dystocia and IDMs have a greater risk of birth trauma resulting from shoulder dystocia. Based on evaluation of reported rates of shoulder dystocia and birth trauma at different birth weights, it has been proposed that it may be reasonable to consider cesarean delivery for fetuses with estimated fetal weights greater than 4500 g. The potential neonatal benefit of cesarean delivery in these cases must be balanced against potential maternal morbidity associated with cesarean delivery. Studies evaluating potential benefit of cesarean delivery for presumed macrosomia estimate that up to 588 elective cesarean deliveries for an estimated fetal weight of 4500 g may need to be performed to prevent one case of a permanent brachial plexus palsy (Garabedian et al., 2010).

Intrapartum Diabetes Management

The goals of intrapartum diabetes management are to maintain strict glycemic control and to avoid ketosis. Titration of an intravenous infusion of short-acting insulin is a common strategy for maintaining blood sugars at less than 140 mg/dL (some expert opinions recommend levels <120 mg/dL). Maintenance of blood sugars at this level may be helpful in reducing neonatal hypoglycemia. Maternal hyperglycemia intrapartum has been shown to be associated with higher rates of neonatal hypoglycemia, probably by worsening the fetal hyperinsulinemic response. After delivery, the IDM will no longer have a steady supply of maternal glucose as a fuel, but higher insulin levels persist.

Maternal Obesity

The worsening obesity epidemic is contributing to the global rise in type 2 diabetes and gestational diabetes, thus resulting in an increased risk of the perinatal complications attributable to diabetes. Importantly, maternal obesity even in the absence of diabetes has been found to be an independent risk factor for adverse obstetric, fetal, and neonatal outcomes. Specifically, maternal prepregnancy obesity has been associated with an increased risk of congenital anomalies, stillbirth, macrosomia, hypertensive disorders of pregnancy (e.g., preeclampsia), stillbirth, cesarean delivery, as well as pediatric obesity (ACOG, 2015).

Obese women have been noted to have offspring with a 2.2-fold increased odds of open neural tube defects as well as an increased

risk of hydrocephalus, cardiovascular anomalies, cleft lip and/or palate, as well as limb reduction anomalies (Stothard et al., 2009). This elevated risk of congenital malformation is likely to be compounded by the presence of pregestational diabetes if there is suboptimal glycemic control. Despite the recognition of elevated risk of congenital malformations in offspring of obese women with diabetes, ultrasound evaluation for fetal anomalies in obese women is more challenging; studies estimate a 20% lower detection rate for anomalies (Dashe et al., 2009; Aagaard-Tillery et al., 2010).

The risk of stillbirth is also elevated in overweight and obese women; in several studies, the risk of perinatal mortality was shown to increase with increasing severity of maternal obesity (Salihu et al., 2007; Aune et al., 2014). Maternal prepregnancy obesity, as defined by a BMI of greater than or equal to 30 kg/m², has been identified as an independent risk factor for macrosomia and LGA birth weight (Willman et al., 1986). In a cohort of singleton pregnancies, both maternal diabetes and maternal obesity were identified as independent risk factors for LGA birth weight; in the case of maternal obesity, the adjusted odds ratio for delivering an LGA infant is 1.6, while for pregestational diabetes, the adjusted odds ratio is 4.4 (Ehrenberg et al., 2004). Given the greater prevalence of obesity as compared with pregestational diabetes, it is likely that the proportion of LGA infants delivered by obese women will exceed that of diabetic women. Similarly to what is observed in macrosomic IDMs, LGA infants born to obese women appear to have increased adiposity as compared with infants of nonobese women; these children may go on to have an increased risk of childhood obesity and metabolic abnormalities (Boney et al., 2005; Catalano et al., 2009).

Neonatal Complications

Hypoglycemia

IDMs are at increased risk of neonatal hypoglycemia; this is one of the more common neonatal morbidities encountered in IDMs, with reports citing rates of neonatal hypoglycemia as high as 25%–50%; studies in which good maternal glycemic control were reportedly achieved suggest a lower incidence of neonatal hypoglycemia in the range of 5%–15% (Cordero et al., 1998). The reported rates of neonatal hypoglycemia have varied in the medical literature; this is probably due to the continued debate about clinically meaningful definitions of hypoglycemia. Severe or persistent hypoglycemia is known to cause adverse neurologic and endocrine sequelae; however, it is not clear what levels of neonatal glucose are optimal to minimize risk of these complications in IDMs. Defining these optimal newborn glucose levels is likely further confounded by the observation that preterm and low birth weight neonates are more likely to have lower blood sugars (Cornblath et al., 2000; Garcia-Patterson et al., 2012).

Most studies have defined neonatal hypoglycemia as blood glucose levels below 35–45 mg/dL, but clearly not all infants who have hypoglycemia as defined by these levels demonstrate evidence of adverse effects (Garcia-Patterson et al., 2012). In a large prospective cohort study evaluating neonates born at GAs of 35 weeks or older, hypoglycemia (defined as a blood glucose concentration of <47 mg/dL) when treated did not appear to be associated with an increased risk of neurosensory impairment when assessed at 2 years of age. It was also notable that the lowest blood glucose concentration observed in these neonates as well as the number of hypoglycemic episodes did not predict the child's

neurodevelopmental outcome at age 2 years (McKinlay et al., 2015). Many infants with hypoglycemia (if defined as blood glucose <40 mg/dL) may initially be asymptomatic. Symptoms attributable to hypoglycemia may include tremor, jitteriness, irritability, lethargy, and hypotonia; severe cases of hypoglycemia may also lead to convulsions, apnea, or cyanosis.

Neonatal hypoglycemia in IDMs is most likely due to fetal hyperinsulinism: i.e., a response to fetal hyperglycemia resulting from maternal hyperglycemia. After birth, the infant no longer receives a steady supply of maternal glucose; if there is hyperinsulinemia originating in utero, then the neonatal period is characterized by a relative imbalance of insulin as compared with neonatal glucose supply. This imbalance leads to a risk of hypoglycemia evolving within the first few hours of life with a nadir in blood glucose levels reported at 1–3 hours of life in most infants.

IDMs with neonatal hypoglycemia have been observed to have elevated cord blood C-peptide and serum insulin levels at birth (Andersen et al., 1985). Based on the pathophysiology of hypoglycemia in IDMs, it is not surprising that poor maternal glycemic control in the third trimester and in the intrapartum period is a predictor of neonatal hypoglycemia (Andersen et al., 1985; Kline and Edwards, 2007). Maternal plasma glucose levels at delivery have been shown to correlate strongly and negatively with neonatal glucose concentrations at 2 hours of life; in observational studies, rates of neonatal hypoglycemia were significantly lower if maternal blood glucose levels were less than 130 mg/dL (Andersen et al., 1985; Flores-le-Roux et al., 2012). Intrapartum maternal hyperglycemia and resulting fetal hyperglycemia probably stimulate the fetal pancreas to release more insulin, with this effect persisting through delivery and for the first few hours thereafter. Macrosomia has also been shown to be a risk factor for neonatal hypoglycemia, with some studies suggesting a prevalence of 30%–50% in LGA IDMs; this observation is not surprising, as excessive fetal growth has also been attributed to the effects of fetal hyperinsulinemia (Maayan-Metzger et al., 2009; Flores-le-Roux et al., 2012).

In addition to optimizing maternal glycemic control throughout gestation, strict maternal glycemic control in labor or in the hours immediately preceding delivery (e.g., if scheduled cesarean section) will help to prevent or reduce rates of neonatal hypoglycemia. Current expert recommendations for maternal intrapartum glycemic control vary; ACOG recommends maintaining maternal blood glucose levels between 70 and 110 mg/dL for pregestational diabetics (ACOG Practice Bulletin, 2005). Postpartum management that emphasizes the importance of early (within the first hour of life) and liberal breastfeeding may also help to prevent neonatal hypoglycemia (Sarkar et al., 2003; Chertok et al., 2009; Maayan-Metzger et al., 2014).

Respiratory Distress

IDMs may also be at greater risk of respiratory complications and respiratory distress syndrome (RDS) as compared with same GA infants born to nondiabetic mothers. This increased risk of respiratory compromise appears to affect even late-preterm and early-term IDMs, though studies evaluating risk of respiratory distress in IDMs at GAs greater than 38 weeks vary in their results. In a large retrospective cohort evaluating infants born at GAs of 34 weeks or greater, gestational diabetes was identified as an independent risk factor for severe neonatal respiratory failure (requiring admission to the neonatal intensive care unit or the need for ventilator support at 24 hours of age) (Vignoles et al.,

2011). The pathophysiology of respiratory distress in IDMs is thought to result from a delay in pulmonary maturation and surfactant production, leading to a relative surfactant deficiency (Singh and Feigelson, 1983). Insulin appears to have a role in regulating fetal lung maturation; in a cell culture model of type II alveolar cells, exposure to elevated levels of insulin reduced choline incorporation into surfactant phosphatidylcholine (Engle et al., 1983). Fetal hyperinsulinemia may have an inhibitory effect on glycogenolysis, which contributes to a decrease in the synthesis of phosphatidylglycerol (PG).

Given these concerns, many experts have recommended that fetal lung maturity be evaluated prior to considering delivery in women with diabetes at GAs less than 38–39 weeks when there is not an absolute indication for delivery (e.g., preeclampsia or non-reassuring fetal testing). Delivery prior to 39 weeks may be considered clinically when there is persistent suboptimal or worsening maternal glycemic control that is not responsive to usual medical therapy or when there is concern for significant risk of adverse fetal outcomes (e.g., in the setting of macrosomia and polyhydramnios). Currently available antenatal tests for evaluating fetal lung maturity require amniocentesis to facilitate the identification or quantification of pulmonary phospholipids or the quantification of lamellar bodies, which are the storage form of surfactant released by type 2 pneumocytes. Amniocentesis performed in the third trimester is generally considered a safe procedure, with low rates of complications that require same-day delivery (Stark et al., 2000). The lecithin/sphingomyelin (L/S) ratio is one of the quantitative tests used to evaluate likelihood of pulmonary maturity. The amniotic fluid concentration of lecithin usually increases in the third trimester, whereas sphingomyelin levels tend to remain relatively stable. L/S ratio values above 2 in the late third trimester have been associated with a high likelihood of pulmonary maturity. L/S ratios are altered by the presence of blood or meconium in the amniotic fluid. PG is one of the last pulmonary phospholipids to be identified in the amniotic fluid; its presence in the amniotic fluid has been associated with pulmonary maturation. Unlike the L/S ratio, the test for identification of PG is not impacted by the presence of blood or meconium in the amniotic fluid. Both the L/S ratio and the PG assay require a significant amount of technical expertise and cost to perform; therefore the lamellar body count (LBC) test, which is automated and more widely accessible, has become increasingly popular as a test of fetal lung maturity. Lamellar bodies are the storage form of surfactant released by type 2 pneumocytes; lamellar bodies are similar in size to platelets so the quantity of lamellar bodies can be estimated using the same automated counter used to obtain platelet counts. LBCs greater than 50,000/μL are positively correlated with pulmonary maturation. If there is blood in the amniotic fluid specimen, the results of the LBC may be affected.

Studies evaluating the performance of the L/S ratio as a predictor of fetal pulmonary maturation in diabetic pregnancies have been mixed, with some studies concluding that using a higher threshold with L/S greater than 3.0 as indicative of lung maturity in diabetic pregnancies performs better (Kitzmillier et al., 1978). Conversely, other studies have demonstrated the appropriateness of utilizing the general threshold of L/S greater than 2.0 as indicative of fetal pulmonary maturation (Kjos et al., 1990; Tabsh et al., 1982). The values of the PG and LBC tests that have been considered indicative of fetal pulmonary maturation in the general population appear to be valid in pregnancies complicated by diabetes. In general, tests of fetal lung maturity have a much better negative predictive value for RDS than positive predictive value.

Antenatal Corticosteroids for Reduction in Risk of Respiratory Distress Syndrome

In clinical settings in which early preterm birth (at GAs <34 weeks) is anticipated, antenatal corticosteroids may be considered to reduce the risk of RDS and other neonatal complications of prematurity. In the setting of maternal diabetes, the decision to administer antenatal corticosteroids must also take into consideration the potential maternal impact of these medications. Corticosteroid administration can lead to maternal hyperglycemia by promoting hepatic gluconeogenesis and impairing insulin sensitivity (Tamez-Perez et al., 2015). Significant maternal hyperglycemia resulting from the administration of antenatal corticosteroids must be anticipated, because if left untreated there may be an increased risk of maternal complications such as DKA in women with type 1 diabetes (Bedalov et al., 1997; Fisher et al., 1997). An evaluation of the impact of antenatal corticosteroid use in pregnant diabetic women demonstrated a significant increase in insulin requirements for the 5 days following medication administration. Peak insulin requirements were noted on days 2–3 after administration, with an approximately 40% increase in insulin dosage needed to achieve glycemic control (Mathiesen et al., 2002).

Because of the potentially adverse maternal effects resulting from corticosteroid administration, women with diabetes were excluded from the recent National Institute of Child Health and Human Development multicenter trial evaluating the role of corticosteroid therapy in pregnancies at risk of late preterm birth between 34 and 36 weeks' gestation. This trial demonstrated a significant decrease in the need for neonatal respiratory support and a decrease in the rate of severe respiratory complications in those infants whose mothers received corticosteroids prior to delivery; however, neonatal hypoglycemia was significantly more common in the group of infants who had been exposed to betamethasone in utero (24% in the betamethasone group vs 15% in the placebo group, RR 1.60, 95% CI 1.37–1.87) (Gyamfi-Bannerman et al., 2016). These results have led ACOG to advise the consideration of betamethasone administration in singleton pregnancies at risk for late preterm birth, but ACOG acknowledges that women with pregestational diabetes were not included in the Antenatal Late Preterm Steroids trial so the effect of late preterm corticosteroids in this population is unknown (ACOG Committee Opinion, 2016). In this setting, the potential adverse effects of late preterm corticosteroids is likely difficult to justify in women with pregestational diabetes.

Hypertrophic Cardiomyopathy

IDMs have an increased risk of developing hypertrophic cardiomyopathy. The most common echocardiographic findings include asymmetric interventricular septal enlargement, with hypertrophy of the ventricular free walls noted to a lesser extent. On average, most series reporting on the prevalence of hypertrophic cardiomyopathy note that 30%–40% of IDMs have evidence of these cardiac changes on imaging, but only approximately 5% of infants will manifest symptoms suggestive of congestive heart failure. Heart failure may be caused by interventricular septal hypertrophy, leading to obstruction of the left ventricular outflow tract. Most symptomatic infants require only supportive care. In almost all cases, the myocardial hypertrophy is found to resolve spontaneously within 6–12 months of life.

The underlying etiology of hypertrophic cardiomyopathy seen in IDMs is still incompletely understood; it is hypothesized to be

related to fetal hyperinsulinemia (Hayati et al., 2004). As noted in other organs, increased insulin and related factors such as IGFs have been found to stimulate hyperplasia and hypertrophy. In myocardial cells, insulin inhibits the enzyme glycogen synthase kinase-3, which is a negative regulator of myocardial growth; its inhibition might contribute to abnormal myocardial hypertrophy. Further evidence in support of fetal hyperinsulinemia in the pathogenesis of hypertrophic cardiomyopathy comes from the observation that infants with congenital hyperinsulinism (in the absence of maternal diabetes) also appear to have an increased risk of hypertrophic cardiomyopathy. In a series of 25 infants with congenital hyperinsulinism who required neonatal echocardiogram evaluation for symptoms (e.g., arrhythmias, auscultated murmurs, etc.), 40% were found to have evidence of hypertrophic cardiomyopathy with features similar to that found in IDMs (Huang et al., 2013). Findings from serial fetal echocardiographic evaluations have also raised the hypothesis that structural cardiac changes may represent an adaptive response to altered fetal cardiac function early in gestation. Fetuses of diabetic mothers demonstrated impaired diastolic function (prolonged isovolumetric relaxation time and lower early/atrial [E/A] ratio) and poorer global cardiac function (increased myocardial performance index or Tei index) as compared with fetuses of nondiabetic mothers. The fetuses of diabetic mothers went on to develop evidence of interventricular septal thickening in the third trimester but had no persistent evidence of cardiac dysfunction later in gestation. (Russell et al., 2008). Maternal metabolic control during organogenesis is known to have a significant impact on fetal cardiac development, as discussed earlier in this chapter.

Predictors of symptomatic cardiomyopathy in IDMs are limited at this time. Despite evidence that supports a role for fetal hyperinsulinemia in the development of hypertrophic cardiomyopathy, the association between maternal glycemic control and this fetal/neonatal complication is not clear. Clinical studies evaluating the correlation between fetal/neonatal hypertrophic cardiomyopathy and maternal HbA_{1c} values have been mixed in their conclusions. Investigators have reported evidence of septal hypertrophy even in fetuses of women with well-controlled diabetes. Third-trimester fetal echocardiography has been used to measure the myocardial performance index (as an indicator of global cardiac function) and the E wave/A wave peak velocity (E/A) ratio at the mitral valve, as an indicator of ventricular diastolic function, in an attempt to identify fetuses of diabetic mothers who are at increased risk of adverse perinatal outcome (including symptomatic cardiomyopathy). In a small series (Bhorat et al., 2014), these fetal echocardiographic measurements appeared to have reasonable sensitivity and specificity for the prediction of a composite of adverse perinatal outcomes, but given the low prevalence of the most serious of these outcomes (symptomatic cardiomyopathy, perinatal death), the predictive value and the cost-effectiveness of these measures are probably limited at this time.

Hypocalcemia and Hypomagnesemia

Calcium and magnesium are actively transported across the placenta to the fetus throughout gestation. At delivery, the transfer of these minerals is terminated and neonatal levels of these minerals are expected to decrease in most infants, but IDMs appear to have an increased risk of more significant declines in levels of calcium and magnesium.

Neonatal hypocalcemia is often defined as a serum calcium level less than 7 mg/dL or an ionized calcium level less than 4.4 mg/

dL (1.1 mmol/L). Studies have historically reported that up to 50% of IDMs may have hypocalcemia in the neonatal period, though more recent reports suggest a lower prevalence of 4%–5% (Cordero et al., 1998). Most affected infants will be asymptomatic. This condition is often found to resolve spontaneously. It is suspected that neonatal hypocalcemia may result from a delayed transition from fetal to neonatal parathyroid action in calcium metabolism as fetal parathyroid glands are relatively inactive until after delivery. The risk of neonatal hypocalcemia is further increased in the setting of prematurity as well as perinatal asphyxia.

Neonatal hypomagnesemia is defined as a serum magnesium level below 1.5 mg/dL. Hypomagnesemia has been reported to affect as many as 40% of IDMs, although most usually remain asymptomatic. Neonatal hypomagnesemia appears to be most clinically relevant in the context of significant hypocalcemia, as concurrent hypomagnesemia makes the treatment of hypocalcemia more difficult. Magnesium deficiency probably has adverse effects on parathyroid function, thus exacerbating hypocalcemia. The pathophysiology underlying neonatal hypomagnesemia is not clear. Some experts have hypothesized that fetal hypomagnesemia may result from lower maternal magnesium levels in the setting of diabetes from increased maternal urinary losses or renal dysfunction.

Clinical signs and symptoms of hypocalcemia and hypomagnesemia are similar to those of hypoglycemia and include jitteriness, irritability, tachypnea, and possibly seizures in severe cases. Unlike hypoglycemia, which often presents within the first few hours of life, symptoms of hypocalcemia and hypomagnesemia typically present later at 24–72 hours after birth (Barnes-Powell, 2007).

Polycythemia

Polycythemia, defined as a venous hematocrit above 65% or hemoglobin greater than 20 g/dL, is also observed more often in IDMs. Polycythemia has been observed in approximately 3% of all infants born at sea level, with a slightly higher prevalence of 5% in infants born at higher altitudes. Among IDMs, the reported prevalence has ranged from 5%–40% (Tyrala, 1996). Fetal hyperglycemia leads to increased catabolism and increased oxygen consumption resulting in decreased oxygen tension. If chronic, this relative fetal hypoxemia is thought to stimulate erythropoiesis, resulting in polycythemia. Some small series have reported an association between maternal diabetic control (as represented by HbA_{1c} levels) and neonatal hematocrit. Higher erythropoietin levels have been noted in the amniotic fluid of women with diabetes. IDMs have also been shown to have increased erythropoietin levels at birth; erythropoietin levels in IDMs have also been shown to correlate with amniotic fluid glucose and insulin levels as well as cord blood insulin levels.

Infants with polycythemia may be at greater risk of complications resulting from hyperviscosity; reported complications include ischemia and infarction such as within the kidneys or within the CNS. These complications attributable to hyperviscosity may explain the increased incidence of renal vein thrombosis and stroke that have previously been reported in IDMs. Polycythemia in utero may also lead to deficient iron stores in the liver, brain, and heart; iron deficiency in these organs may then predispose to myopathies and altered neurodevelopment.

Infants with clinically significant polycythemia are likely to appear plethoric and may demonstrate sluggishness or lethargy. Treatment is currently initiated on the basis of symptoms and clinical status; treatment is not recommended on the basis of hematocrit value alone as the hematocrit level does not appear to

correlate well with clinical hyperviscosity. Reported therapies include intravenous fluid administration and possible consideration of partial volume exchange transfusion in some severe cases.

Hyperbilirubinemia

IDMs also appear to be at greater risk for hyperbilirubinemia than infants born to nondiabetic mothers. In studies that defined hyperbilirubinemia as a serum bilirubin level greater than 12 mg/dL or any bilirubin level requiring phototherapy, the prevalence of hyperbilirubinemia in IDMs was 25% (Cordero et al., 1998); other series report a hyperbilirubinemia prevalence of 10%–13% in IDMs. This increased risk might be attributable to polycythemia (larger source of bilirubin to be conjugated by the liver prior to excretion), ineffective erythropoiesis with an increased red blood cell turnover, as well as to immaturity of hepatic bilirubin conjugation and excretion. Macrosomic IDMs appear to have the greatest risk of hyperbilirubinemia; this probably reflects the role of poor maternal glycemic control during pregnancy as IDMs of these women are most likely to be macrosomic and polycythemic.

Breastfeeding

Breastfeeding is important to the health and well-being of all children; the benefits of breastfeeding may be even greater in IDMs. As mentioned previously, early and liberal breastfeeding in the immediate neonatal period may help to prevent hypoglycemia or effectively treat mild cases of hypoglycemia.

The positive effects of breastfeeding for IDMs are likely to extend significantly beyond the neonatal period. Intrauterine exposure to maternal diabetes and/or obesity appears to be associated with an increased risk of childhood obesity; successful breastfeeding of durations greater than or equal to 6 months may mitigate some of this risk. There has been increasing evidence of the long-term impact of the intrauterine environment on the development of adulthood diseases. Several cohort studies have suggested an increased risk of diabetes and obesity in childhood or adolescence in the offspring of diabetic mothers (Dabelea et al., 2000; Damm, 2009; Vohr and Boney, 2008). Studies conducted in the Pima Indian population demonstrated that offspring of diabetic mothers had a significantly increased risk of type 2 diabetes (12-fold increased odds) when compared to offspring of nondiabetic mothers (Pettitt et al., 1991). Offspring of diabetic mothers also were noted to be heavier than offspring of nondiabetic mothers when evaluated at ages 5–9 years and at 10–14 years; the greater risk of obesity in offspring of diabetic women persisted even among those who had a normal birth weight (Pettitt et al., 1987).

A longer duration of breastfeeding has been associated with a decreased risk of offspring childhood obesity. A metaanalysis of studies conducted in general populations demonstrated that each month of breastfeeding was associated with a 4% decrease in risk of being overweight in childhood (Harder et al., 2005). In offspring of diabetic mothers, breastfeeding duration of greater than or equal to 6 months has also been associated with decreased measures of adiposity such as waist circumference and measures of visceral and subcutaneous abdominal fat (Crume et al., 2011, 2012). The obstetric community has increasingly recognized the importance of recommending and advocating for breastfeeding among diabetic mothers; these women are anticipated to benefit from additional medical support, given the effects of breastfeeding on diabetes. During lactation, women with diabetes have a significant decrease in insulin or oral hypoglycemic medication requirements; in fact,

women (especially type 1 diabetic women) are at an increased risk of hypoglycemia during breastfeeding. Predelivery counseling by their obstetric and/or endocrinologic providers can help to facilitate an appropriate medical management and safety plan during lactation; close follow-up during the postpartum period with attention to issues unique to lactation in the context of diabetes can help to optimize breastfeeding success.

Maternal Medical Disorders of Fetal Significance

THOMAS F. KELLY

KEY POINTS

- Diagnostic imaging carries a risk of fetal radiation exposure. However, in most cases the actual fetal dose in properly performed procedures is low. While x-ray and computed tomography imaging should be avoided during pregnancy if possible, these studies are not contraindicated if needed.
- Delay in diagnosis of medical and surgical conditions in pregnancy is more common, in part because certain signs and symptoms may be similar to those related to pregnancy.
- The previously utilized pregnancy drug classification is being abandoned because most drugs have no definitive human studies documenting their safety or harm.
- Adverse pregnancy outcomes in patients with lupus are more frequently seen in those with renal disease, antiphospholipid antibody syndrome, thrombocytopenia, and active disease.
- Immune thrombocytopenia is associated with a potential risk of neonatal thrombocytopenia, which is not predicted by maternal disease status. However, gestational thrombocytopenia does not incur the same risk.
- Cardiovascular disease in pregnancy is increasing in frequency and has become a major contributor to maternal mortality.
- The evaluation and management of most cancers should not be delayed for the sake of pregnancy and for fear of harm to the fetus. Surgery and most chemotherapeutic agents have been successfully used during the second and third trimesters.
- Epilepsy is associated with an increased rate of poor reproductive outcomes regardless of medication use. Medications used to control seizures do incur an increased rate of fetal anomalies, but the benefits to mother and fetus usually outweigh their risk.
- Selective serotonin reuptake inhibitors are considered first-line medication therapy for depression in pregnancy.

Pregnancies complicated by an underlying maternal medical condition increase the potential of a suboptimal perinatal outcome. The trend of delaying conception has undoubtedly increased the rate of medical comorbidities. Therefore the obstetrician is increasingly faced with patients affected by a medical problem that is unrelated to pregnancy. While diagnostic and therapeutic options for a nonpregnant adult in most cases can be effectively applied during pregnancy, there are concerns about whether these will adversely affect the fetus or newborn.

Furthermore, the alterations of maternal anatomy and physiology during pregnancy may require adjustments of therapeutic options.

Two simple (but potentially difficult to answer) questions should be addressed when a specialist is caring for a pregnant patient with a known medical problem. First, is the condition itself affected by the anatomic or physiologic alterations of pregnancy? Secondly, how does the medical problem affect the women, her fetus, or the ultimate perinatal outcome? A further concern is how to evaluate a newly suspected medical problem during pregnancy. Pregnancy itself can be a confounder as many symptoms experienced are similar to those of certain medical or surgical conditions, leading to either a lack or delay of diagnosis. Providers may be reticent to perform needed imaging studies, to proceed with indicated surgical procedures, or to prescribe medications over concerns regarding risk to the fetus. Delays of diagnoses of de novo medical problems due to pregnancy have been reported. Unfortunately, in some cases, lack of timely recognition and initiation of appropriate therapy may result in poor maternal or fetal outcomes.

General Principles in the Diagnosis and Management of Medical Complications During Pregnancy

Diagnostic Radiation

Diagnostic radiography may be associated with fetal radiation exposure even when studies target maternal anatomy remote from the pregnant uterus (Table 11.1). The fetal consequences of radiation exposure are both dose and time dependent (Table 11.2). However, for most diagnostic procedures, actual fetal exposure is relatively low. The practitioner should limit the amount of radiographic testing if at all possible, but indicated studies should never be withheld because of pregnancy. Lead shielding of the abdomen and pelvis and careful selection of the type of study should be undertaken to minimize the fetal dose. If the amount of fetal exposure is less than 5 rad, there appears to be no significant increased risk of malformations. There is, however, a slightly increased risk of childhood cancer if the fetus is exposed to doses of greater than 10 mGy (Doll and Wakeford, 1997). To simplify the various measures of exposure, 1 radiation absorbed dose (rad), 1 Roentgen equivalents man (rem), 10 milliGray (mGy), and 10

TABLE 11.1 Estimated Conceptus Doses From Selected Imaging Studies

| Radiographic and Fluoroscopic Examinations | Typical Conceptus Dose (mGy) |
|--|------------------------------|
| Cervical spine (anteroposterior, lateral) | <0.001 |
| Extremities | <0.001 |
| Chest (posteroanterior, lateral) | 0.002 |
| Thoracic spine (anteroposterior, lateral) | 0.003 |
| Abdomen (anteroposterior) | |

milliSievert (mSv) can be considered equivalent (Wang et al., 2012). Iodinated contrast agents have not been shown to be teratogenic. There is a theoretical concern of fetal hypothyroidism, but there have been no reported cases resulting from the use of these agents (Tirada et al., 2015). Use of these agents may also be justifiable with the aim of reducing further radiation exposure from repeated studies.

Magnetic resonance imaging (MRI) has not been shown to have adverse effects on the fetus. However, its safety has yet to be definitively determined. It is generally recommended that MRI be avoided in the first trimester, unless the benefit outweighs the risk (Duchene et al., 1991; Kanal et al., 2007). Gadolinium contrast should be used during pregnancy with extreme caution, given the lack of human safety data and unknown half-life in the fetal compartment (Kanal et al., 2007).

Surgery During Pregnancy

Approximately 2% of pregnant women require surgery for a non-obstetrical condition. The most common indications are appendicitis and cholecystitis (Juhász-Böss et al., 2014). Indicated surgery during pregnancy is relatively safe. The potential for adverse perinatal

consequences is increased when compared with patients not requiring surgery. However, delay of needed procedures in some cases clearly increases the risk of poor maternal or fetal outcome. A recent review of 54 papers regarding surgery during pregnancy (Cohen-Kerem et al., 2005) concluded the following:

1. The risk of maternal death is low.
2. Surgery and general anesthesia do not appear to be major risk factors for spontaneous abortion.
3. Elective termination rates are similar to the general population.
4. The rate of congenital anomalies does not appear to be increased.
5. Acute appendicitis, particularly with peritonitis, appears to be a risk of surgery-induced labor or fetal loss.
6. Urgent surgical procedures should be performed when needed.

Since appendectomy is the most common nonobstetric surgery performed during pregnancy (1 in 766 births), the data regarding outcomes are relatively robust. The rates of fetal loss and early delivery are higher for complex appendicitis (6% and 11%, respectively) versus simple appendicitis (2% and 4%, respectively). Pregnancy confounds the diagnosis and, potentially, the therapy with a reluctance to operate. The negative appendectomy rate in pregnancy is higher when compared with nonpregnant cases (23% vs 18%). Unfortunately, surgery for appendicitis and the finding of a normal appendix is still associated with an increased risk of loss (3%–4%) (McCory et al., 2007; Ito et al., 2012). While laparoscopy is being utilized increasingly during pregnancy, there may be an associated increased risk of loss when compared with laparotomy for suspected appendicitis (Wilasrusmee et al., 2012). However, the type of surgical procedure, whether laparoscopic versus open, should be determined by the surgeon, preferably in consultation with the obstetrics team.

Guidelines to optimize outcome for pregnant patients undergoing surgery are relatively simple. Anesthetic options are unchanged when compared with nonpregnant patients, as both regional and general anesthesia can be safely administered. However, if general anesthesia is being used, the maternal airway must be protected to prevent aspiration. Gastrointestinal motility is reduced in pregnancy and the stomach may contain significant residual contents hours after eating. A lateral decubitus position is preferred to optimize maternal venous return and uteroplacental perfusion. Preoperative counseling with an obstetrician and neonatologist is recommended, particularly if the gestational age is greater than or equal to 22 weeks to give the surgical team direction regarding interventions should fetal distress be encountered. Fetal heart rate monitoring, if feasible, can also facilitate assessment of fetal status.

Medication Usage

Maternal medication use during pregnancy requires the provider to understand two basic principles:

- Alterations of maternal anatomy and physiology may alter the effective dose.
- Maternal medications may enter the fetal circulation with resulting fetal exposure.

There are significant physiologic alterations in pregnancy which may alter the bioavailability, distribution, clearance, and half-life of a medication. Absorption is altered due to nausea and vomiting, gastric volume and pH changes, increased gastrointestinal transit time, and differences in activity of drug-metabolizing enzymes in the gut. Increased body weight and plasma volume as well as reduced albumin alter the volume of distribution. Hepatic and placental enzymatic activity and increased glomerular filtration

TABLE 11.2 American College of Radiology Summary of the International Commission on Radiological Protection Suspected in Utero-Induced Deterministic Radiation Effects

| Menstrual or Gestational Age | Conception Age | RADIATION DOSE | | |
|-------------------------------|-------------------------------|------------------|--|--|
| | | <50 mGy (<5 rad) | 50–100 mGy (5–10 rad) | >100 mGy (>10 rad) |
| 0–2 weeks (0–14 days) | Before conception | None | None | None |
| 3rd and 4th week (15–28 days) | 1st–2nd week (1–14 days) | None | Probably none | Possible spontaneous abortion |
| 5th–10th week (29–70 days) | 3rd–8th week (15–56 days) | None | Potential effects are scientifically uncertain and probably too subtle to be clinically detectable | Possible malformations increasing in likelihood as dose increases |
| 11th–17th week (71–119 days) | 9th–15th week (57–105 days) | None | Potential effects are scientifically uncertain and probably too subtle to be clinically detectable | Increased risk of deficits in intelligence quotient or mental retardation that increase in frequency and severity with increasing dose |
| 18th–27th week (120–189 days) | 16th–25th week (106–175 days) | None | None | Intelligence quotient deficits not detectable at diagnostic doses |
| >27 weeks (>189 days) | >25 weeks (>175 days) | None | None | None applicable to diagnostic medicine |

rates will influence drug clearance (Zhao et al., 2014). Examples include levothyroxine and phenytoin, both medications in which the dose often must be increased through gestation.

The awareness that certain maternal drugs may induce congenital malformations, notably thalidomide in the early 1960s, led the Food and Drug Administration (FDA) to develop a maternal drug classification system (categories A–D + X). The premise for such a classification was to provide prescribing providers with a brief summary of potential fetal risk. Most drugs (65%–70%) were category C, which meant that while animal studies had shown adverse effects, there were no adequate human studies (Greene, 2015). Half of all pregnant women receive drugs in categories C and D (Andrade et al., 2004). Since so many drugs are category C, providers may assume that they are safe. The FDA has recently published the “Pregnancy and Lactation Labeling Rule,” effective 2015, eliminating the ABCDX classification for any new drug applications. The rule will expand for prescription drugs approved after 2001 (US Food and Drug Administration, 2006). The new subheadings under the pregnancy subsection will include exposure registry, risk summary, clinical considerations, and data. It is a reasonable assumption that, with the exception of a few medications, the most commonly prescribed drugs have some theoretical or proven fetal risk. Their choice and usage during pregnancy should be dictated by the premise that the maternal benefits clearly outweigh the fetal risk.

Autoimmune Disorders

Systemic rheumatoid illnesses are seen more commonly in women than men and with presentations commonly in young adulthood and middle age. Therefore pregnancy complicated by an autoimmune condition is common. There are an estimated 4500 pregnancies complicated by systemic lupus erythematosus (SLE) in the United States annually (Ramires de Jesus et al., 2015). Other autoimmune conditions seen during pregnancy include rheumatoid arthritis and scleroderma. While perinatal implications may differ, depending on the diagnosis, there are enough similarities among most rheumatologic disorders that there are common themes in maternal

management, including work-up, medication usage, and fetal screening. Furthermore, some patients may have findings consistent with an autoimmune condition but lack enough criteria to warrant a specific diagnosis. Finally, there are individuals lacking clinical rheumatologic manifestations that exhibit autoantibodies that have maternal, fetal, or neonatal implications. The nuances of all autoimmune disorders are too broad to allow discussion in this chapter. Therefore the focus will be on SLE and common antibody disorders with specific perinatal implications.

Systemic Lupus Erythematosus

SLE or lupus is a disease that can affect multiple organs. Early studies reported increased risks of prematurity, preeclampsia, and lupus flare, and therefore pregnancy was ill-advised. However, while recent literature has suggested more reasonable outcomes, there is an increased risk of prematurity (47%), fetal loss (23%), miscarriage (16%), growth restriction (14%), and early (13%) and late (12%) preeclampsia (Clark et al., 2005; Alijotas-Reig et al., 2015). In the absence of antiphospholipid antibody syndrome (APS) or significant renal insufficiency, fertility does not seem impacted (Stanhope et al., 2012). As with most autoimmune conditions, there is not uniform agreement on whether pregnancy alters the disease course. However, risk factors associated with a lupus flare include active disease within 6 months before conception, history of multiple flares, and discontinuation of hydroxychloroquine.

Risk factors for poor pregnancy outcomes in patients with lupus include proteinuria, renal insufficiency, APS, thrombocytopenia, or active maternal disease at the time of conception (Strojan and Baer, 2012). Those with nephritis, APS, or who have anti-Sjögren syndrome related-antigen A (anti-SSA or anti-Ro antibodies) may have increased risks of altered perinatal outcomes. Adverse outcomes include spontaneous abortion and intrauterine growth restriction (IUGR), and the risk of superimposed preeclampsia and stillbirth are potentially increased. Therefore assessment of the patient's baseline disease activity, as well as exploration for evidence of multiorgan system dysfunction, is vital to aid in counseling and

TABLE 11.3 Laboratory Testing of Patients With Systemic Lupus Erythematosus During Pregnancy

| Timing | Purpose | Test | Comment |
|---|---|---|---|
| Preconception or initial prenatal visit | Screen for organ system dysfunction and baseline for comparison should a lupus flare or preeclampsia be suspected | Urinalysis | Assessment of renal disease activity |
| | | 24-hour urine for total protein or urine protein:creatinine ratio | 24-hour urine collection for proteinuria recommended if abnormal protein:creatinine ratio |
| | | Complete blood count | Assess for thrombocytopenia |
| | | Chemistry panel | |
| | Screen for risk of neonatal lupus syndrome | Anti-SSA (Ro) and Anti-SSB (La) antibodies | If present, screen for fetal congenital heart block |
| | Screen for disease activity and baseline for comparison should a lupus flare or preeclampsia be suspected | Anti-double-stranded DNA antibody Complement levels | Complement levels may increase in a normal pregnancy |
| Monthly | | Urinalysis | Urine protein:creatinine ratio if urinalysis suspects proteinuria |
| | | Creatinine | If prior history of lupus nephritis or prior renal dysfunction is noted |
| Every trimester | | Anti-double-stranded DNA antibody Complement levels | |
| | | Complete blood count | |
| | | Chemistry panel | |

management. Comanagement with rheumatologists and/or nephrologists is vital to improve maternal and fetal outcomes.

Initial prenatal evaluation of a patient with lupus includes taking a history, such as disease activity, organ system involvement, and current medical therapy. The latter is important in determining whether there is an increased fetal risk, as some medications used are generally contraindicated during pregnancy (methotrexate, mycophenolate mofetil). Fortunately, most patients planning pregnancy are not using these agents. Prednisone, azathioprine, and hydroxychloroquine are more commonly used medications with reasonable safety profiles during pregnancy.

Chemical screening for disease activity should be performed. This includes anti-double-stranded DNA and complement levels. Antiphospholipid antibodies, anti-Ro, and anti-La (otherwise known as anti-Sjögren syndrome related-antigen B or anti-SSB) antibodies should be measured. The patient should also have baseline assessments for proteinuria, renal function, hepatic enzymes, and platelet count not only to assess her status but also to formulate a baseline profile (Table 11.3). Since a lupus flare may mimic preeclampsia, comparison of her repeated studies against those obtained earlier may be helpful, as the management of these two conditions differs.

Medication management, including type and amount, is dictated by disease activity and the presence of APS. Most patients are managed with steroids, hydroxychloroquine, or azathioprine, and alterations of these should probably not be dictated by pregnancy. While there may be theoretical concerns with their usage, these drugs have to be balanced against the risk of uncontrolled lupus (Table 11.4).

Assessment of disease activity should include the presence of maternal symptoms as well as regular complement and anti-double-stranded DNA levels. Regular assessment of fetal growth by ultrasound and antepartum fetal testing should be initiated in the latter third trimester. A sudden increase in the patient's blood

pressure or level of proteinuria must be regarded as a potential sign of either a lupus flare or preeclampsia. At times, differentiation between the two is challenging, but every effort should be made to do so, as therapies for both are different.

Antiphospholipid Antibody Syndrome

APS was originally described as an autoimmune disease characterized by circulating antiphospholipid antibodies (aPL) and venous thrombosis, recurrent pregnancy loss, and occasionally thrombocytopenia (Hughes, 1983). This disorder may be isolated or associated with other autoimmune diseases. The presence of aPL is found in about 1%–5% of healthy women. However, these antibodies are found in 15% of women who have recurrent abortions (Ruiz-Irastorza et al., 2010) and in 30%–40% in those with SLE (Ünlü et al., 2015). The presence of aPL in the latter is a risk factor for a poor pregnancy prognosis.

Few women with aPL will develop disease, and the prevalence of APS is estimated to be only 50/100,000 (Gomez-Puerta et al., 2014). The diagnosis of APS must include clinical criteria (vascular thrombosis, unexplained death of a morphologically normal fetus >10 weeks' gestation, premature birth <34 weeks due to preeclampsia or placental insufficiency, or ≥three otherwise unexplained abortions <10 weeks) as well as the presence of aPL (lupus anticoagulant, anticardiolipin antibody, or anti-β₂-glycoprotein antibody) on greater than two occasions, at least 12 weeks apart (Miyakis et al., 2006). For those with a prior history of venous or arterial thrombosis, prophylactic anticoagulation with heparin throughout pregnancy and continuing through 6 weeks' postpartum is usually recommended. In patients with recurrent pregnancy loss, low-dose aspirin and heparin may reduce pregnancy loss by 50% (Empson et al., 2002). Therefore even in the absence of a thrombotic history, in those with a history of stillbirth or recurrent pregnancy loss,

TABLE 11.4 Medications Used for Rheumatic Disorders

| Commonly Used During Pregnancy | Maternal and Fetal Outcomes | Recommendations |
|--|--|--|
| Prednisone, prednisolone | Possible risk for orofacial clefts | Treatment of flares or maintenance therapy |
| Fluorinated corticosteroids (betamethasone, dexamethasone) | Cross the placenta. May be associated with poor fetal growth or adverse neurologic outcomes if used in multiple doses | Use only if fetal treatment is being considered (neonatal lupus syndrome) |
| Hydroxychloroquine | Considered safe in doses commonly used in SLE and RA | Safe to continue in pregnancy |
| Azathioprine | May be associated with IUGR, transient immune alterations | Long track record of use in pregnancies complicated by SLE. Safe to continue if necessary |
| Nonsteroidal anti-inflammatory drugs | May be associated with fetal ductus arteriosus constriction and impaired renal function with third trimester use | Avoid in third trimester. Limit use to very short duration (48–72 hours) |
| Sulfasalazine | No increased risk in doses commonly used in RA | Use folic acid supplementation preconception and during pregnancy |
| Heparin | Does not cross placenta | If using low-molecular-weight heparin, may require changing to unfractionated heparin after 36 weeks for maternal anesthesia |
| IVIg | No identifiable fetal risk | May be used in refractory cases of immune thrombocytopenia |
| Contraindicated | | |
| Methotrexate | Increased risk for congenital malformations | Conception should be delayed for at least 3 months after last dose |
| Leflunomide | Embryotoxicity | Discontinue 2 years prior to conception |
| Mycophenolate mofetil | Increased risk for congenital malformations | |
| May Be Used | | |
| Cyclosporine | Often used in patients with organ transplants. No increased risk of congenital malformations | May be used in patients with SLE |
| Cyclophosphamide | Use in first trimester associated with fetal anomalies or loss. Second- and third-trimester use may be associated with fetal growth issues and impaired neurologic development | Use only if mother's life is at risk and other options have been exhausted |
| Rituximab | Associated with transient B-cell depletion in the second and third trimesters | Inadequate safety data to support routine use in pregnancy Neonatal live virus vaccination should be delayed by 6 months |

prophylactic heparin and low-dose aspirin should be offered during pregnancy for up to 6 weeks' postpartum ([American College of Obstetrics and Gynecology, 2012](#)).

Neonatal Lupus

Anti-Ro and anti-La antibodies can be present in asymptomatic women. The former are more often seen in women with Sjögren syndrome but can be also found in women with other autoimmune disorders ([Mecacci et al., 2007](#)). These antibodies cross the placenta

and have been associated with congenital heart block. In the absence of a prior infant with congenital heart block, the prospective fetal risk is low, at 2%. However, in patients with a prior history of an affected fetus or neonate, the recurrence risk is 15%–20% ([Izmirly et al., 2010](#)). The morbidity and mortality of these infants are significant, the latter ranging between 10% and 29% ([Saxena et al., 2014](#)). Other consequences include potential need for a pacemaker or cardiac transplantation.

The injury to the atrioventricular node most often occurs between 16 and 24 weeks, and there is the potential for fibrosis that can

extend to the endocardium and myocardium. No prenatal interventions have been shown to reverse complete heart block (Eliasson et al., 2011). However, there may be some improvement in outcome with the use of fluorinated steroids if second-degree heart block is detected. There are potential fetal consequences of maternal steroids, including adrenal insufficiency, as well as neurodevelopmental and growth abnormalities (Saxena et al., 2014). It is suggested that women exhibiting these antibodies undergo fetal echocardiography beginning in the second trimester (16–18 weeks) and repeated every 1–2 weeks until 28 weeks (Donofrio et al., 2014). In those with a prior child affected with congenital heart block, use of hydroxychloroquine may be associated with a reduced risk of recurrence (Izmirly et al., 2012).

Immune Thrombocytopenia

Approximately 7%–10% of pregnancies are complicated by thrombocytopenia (Meyers, 2012). The most common etiology is gestational thrombocytopenia (75%), followed by preeclampsia (15–20%) and immune thrombocytopenia (ITP) (3%). By definition, ITP is immune mediated, and the responsible antibody may cross the placenta. The incidence is approximately 1/1000 pregnancies (Gill and Kelton, 2000). It is associated with an increased risk of neonatal thrombocytopenia, with 15%–50% of newborns having platelets less than $100 \times 10^9/L$, 8%–30% less than $50 \times 10^9/L$, and 1%–5% less than $20 \times 10^9/L$ (Meyers, 2012). Unfortunately, there is no reliable variable that accurately predicts the potential for neonatal thrombocytopenia; hence a number of interventions had been proposed in the past to reduce the risk of spontaneous fetal or neonatal bleeding. Strategies such as performing routine cesarean section, fetal scalp platelet assessment in labor, or percutaneous fetal scalp platelet counts were not found to be helpful and were potentially associated with increased maternal or fetal morbidity. Therefore it is recommended that delivery mode should not be altered for the diagnosis of ITP (Payne et al., 1997).

Maternal management for this condition in the first and second trimesters of pregnancy is essentially unchanged when compared with a nonpregnant patient (Piatek et al., 2015). If the maternal platelet count is greater than $30,000/\mu L$, no treatment is necessary. Below this threshold, or if there is evidence of spontaneous bleeding, corticosteroids and intravenous immunoglobulin are usually first-line therapies. Both are relatively safe in pregnancy and usually associated with a good maternal response. Refractory cases are much more difficult to manage. Options of large-dose anti-D antibodies have been tried. Splenectomy is usually a last resort but can be performed in the second trimester or at the time of cesarean section (Piatek et al., 2015).

Gestational thrombocytopenia (GTP) is generally a benign condition that sometimes can be difficult to delineate from ITP. However, the salient features include a lack of prior maternal history of severe thrombocytopenia and a maternal platelet count that is usually above $80,000/\mu L$. Other potential causes for a low platelet count should be explored, including severe preeclampsia, autoimmune disease, medication usage, and viral illness. True GTP has no associated risk of neonatal thrombocytopenia. The one potential consequence of GTP may be the reluctance of some anesthesiologists to place a regional anesthetic if the platelet count is too low.

Heart Disease

Heart disease has now become a leading cause of maternal mortality, with cardiomyopathy and acquired cardiovascular diseases

contributing to 26% of maternal deaths in the United States (McGregor et al., 2015). This increase may be due to the more rigorous evaluations of maternal mortality cases than were previously performed, as well as the older, aging pregnant population. In 1970, approximately 1% of first-time mothers were greater than 35 years old. Two decades later, this incidence had increased to 8%. Advances in age are often accompanied by comorbidities such as diabetes, hypertension, and obesity.

Hemodynamic alterations of pregnancy begin early in gestation. Maternal blood volume increases by 50%, with an accompanied decrease in systemic vascular resistance. The cardiac output increases by 30%–50% and heart rate by 15%. The labor process further increases cardiac output (Ouzounian and Elkayam, 2012; Lewey and Haythe, 2014). Furthermore, there are intra- and extravascular fluid shifts that occur after delivery. A previously compromised heart may not tolerate these changes. Attempts to stratify maternal risk have resulted in various scoring systems. The World Health Organization (WHO) classification defines risk based on cardiac condition. However, it is recognized that pregnancy-related risks may be additive: thus a “lower risk” WHO classification of 1 or 2 may be upgraded in the presence of cyanosis, low ejection fraction, or prior cardiovascular event. The highest risk (WHO 4) includes individuals with pulmonary hypertension, severe left ventricular dysfunction, previous peripartum cardiomyopathy with residual impairment of left ventricular dysfunction, left heart obstruction, or Marfan syndrome with a dilated aorta (Thorne et al., 2006). In these patients, pregnancy is not advisable given the high risk of maternal mortality.

Cardiomyopathy

Cardiomyopathy obviously can predate pregnancy, but a form of this condition is unique to gestation. Peripartum cardiomyopathy requires the onset to occur within 1 month prior to delivery or within 5 months after. It is estimated to occur in 1/3000 live births (Mielniczuk et al., 2006). The incidence is higher in African-American women, and other risk factors include hypertension, parity, and multiple gestations (Lewey and Haythe, 2014). The etiology is unknown but potentially mediated by inflammation, autoimmune processes, endothelial dysfunction, and oxidative stress (McGregor et al., 2015). Presentation may be indolent, as symptoms may mimic those commonly encountered in pregnancy. Furthermore, patients with preeclampsia can have significant left-ventricular dysfunction and pulmonary edema, which may confuse the picture, albeit more transiently.

The work-up includes an electrocardiogram. There is a high prevalence of abnormalities in peripartum cardiomyopathy. Echocardiography may reveal depressed left-ventricular function and dilation. Usually the ejection fraction is less than 45% (Lewey and Haythe, 2014). B-type natriuretic peptide levels are normally increased in pregnancy, but there can be a further increase as a consequence of left-ventricular end-diastolic pressure (McGregor et al., 2015). Treatment is supportive and similar to that of preexisting dilated cardiomyopathy. Complications include cardiogenic shock, arrhythmias, thromboembolism, and death. While 25%–50% of patients with peripartum cardiomyopathy may recover by 6 months, one quarter do not improve. The mortality may approach 15% (McGregor et al., 2015). There is an increased risk in subsequent pregnancies, particularly in those who have not had full recovery of reduced ejection fraction and heart failure (Elkayam et al., 2001).

Congenital Heart Disease

Congenital heart disease (CHD) affects approximately 1% of the population (Hoffman and Kaplan, 2002). In the last decade, there has been a significant increase in the prevalence of CHD complicating deliveries from 6.4–9 per 10,000 hospitalizations (Thompson et al., 2015). This is not surprising given the advances in surgical intervention that have improved long-term outcomes and numbers of patients reaching childbearing age. With the exception of hypertensive disorders and thromboembolic events, obstetric complications do not seem to be increased in these patients. However, cardiac complications are found in about 11% of patients and include arrhythmias, heart failure, and cardiovascular events (Drenthen et al., 2007). Myocardial infarction, cerebrovascular accidents, and mortality were noted in about 2% of patients. In those patients with more complex CHD, including Ebstein's anomaly, transposition of the great vessels, pulmonary atresia with ventricular septal defects, and Eisenmenger syndrome, the preterm delivery rate ranged between 22% and 65%. The offspring mortality is higher, probably caused by prematurity. The infants have a higher incidence of CHD, between 0.6% and 8%, depending on the maternal lesion (Drenthen et al., 2007).

Women with CHD should be evaluated before conception to advise them of the maternal and fetal risks of pregnancy. Many patients have limited or inaccurate knowledge of their disease. The history of the actual defect and subsequent surgical and other interventions should be obtained. Electrocardiography and echocardiography should be performed. The latter should focus on ventricular and valve functions, pulmonary artery pressure, and the presence of any prosthetic material. Since about 18% of patients have a defined chromosomal or Mendelian abnormality, formal genetic screening should be performed (Brickner, 2014).

Pregnancy management requires a multidisciplinary team, including cardiology, high-risk obstetrics, and anesthesiology. If necessary, cardiac catheterization or percutaneous interventions can be considered. Cardiopulmonary bypass can be performed during pregnancy, but there is an increased risk of prematurity and fetal death, particularly with urgent, high-risk surgery and maternal comorbidity (John et al., 2011). Medical control of arrhythmias, if necessary, is usually safe. However, use of β -blocker or calcium channel blocker may be associated with suboptimal fetal growth. In most cases, vaginal delivery is preferred. Cesarean section may be considered for women with severe aortic stenosis or pulmonary hypertension.

Coronary Artery Disease

Coronary artery disease is a significant cause of maternal mortality. In a recent survey, it may account for up to 20% of maternal cardiac deaths (CMAC, 2011). Acute myocardial infarction may complicate up to 6/100,000 pregnancies (James et al., 2006). In the UK data, all of the women who died had at least one risk factor for coronary artery disease. Unfortunately, in half of all women who died of ischemic heart disease, their care was deemed substandard (CMAC, 2011), possibly because of symptoms otherwise attributed to pregnancy or a reluctance to pursue a work-up. It appears that spontaneous coronary artery dissection is more common during pregnancy. Patients with ST segment elevation myocardial infarction should be treated similarly to those who are not pregnant. This includes percutaneous coronary intervention (Emmanuel and Thorne, 2015). If stenting is required, bare metal stents should preferably be used to minimize the need for long-term

dual antiplatelet therapy (Regitz-Zagrosek et al., 2011). Aspirin and clopidogrel appear to be safe in pregnancy. Longer-duration antiplatelet therapy is generally recommended if a drug-eluting stent is placed. Once clopidogrel is no longer deemed necessary, single-agent antiplatelet therapy with aspirin is appropriate. β -Blockers are relatively safe to use in pregnancy but carry a theoretical risk of suboptimal placental perfusion.

Renal Disease

Chronic kidney disease (CKD) is increasing in prevalence, affecting up to 3% women of childbearing age (Piccoli et al., 2010). It is estimated that 1/750 pregnancies is complicated by stages 3–5 CKD (Williams and Davison, 2008) (Table 11.5). Since there is no accurate ability to measure glomerular filtration rate in pregnancy, women with CKD have been arbitrarily classified into three categories based on the serum creatinine level: mild, less than 1.5 mg/dL; moderate, 1.5–2.5 mg/dL; and severe, greater than 2.5 mg/dL (Vellanki, 2013). Whether the newer staging of CKD is better than the latter classification in predicting pregnancy outcomes is unknown.

Pregnancy may influence the rate of decline of renal function. While it appears unlikely when the baseline creatinine is less than 1.5 mg/dL, patients with hypertension are more likely to develop progressive disease (Jungers et al., 1995). However, the same cannot be said for those with moderate impairment (creatinine >1.5 mg/dL). A significant risk of deterioration of maternal renal function can be seen in up to 40% of patients with progression to end-stage disease in 10% (Jones and Hayslett, 1996). The risk of irreversible deterioration of renal function is significant in those with marked impairment of renal function irrespective of the type of disease when accompanied by uncontrolled hypertension (Jungers et al., 1991).

When compared with women without CKD, those with kidney disease have a 52% increased odds of preterm delivery, 33% increased odds of cesarean section, 71% increased odds of neonatal intensive care unit (NICU) admission, and a twofold increased odds of low birth weight (Kendrick et al., 2015). The effect of mild-to-moderate CKD on pregnancy is dependent on the degree of renal impairment and the presence of underlying hypertension. In patients with mild renal dysfunction, successful outcomes are usually above 80% but with a complication rate of 26% (Lightstone,

TABLE
11.5

Stages of Chronic Kidney Disease

| Stage | Description | Glomerular Filtration Rate (mL/min ²) |
|-------|---|---|
| 1 | Kidney damage with normal or raised GFR | >90 |
| 2 | Kidney damage with mildly lower GFR | 60–89 |
| 3 | Moderately lower GFR | 30–59 |
| 4 | Severely low GFR | 15–29 |
| 5 | Kidney failure | <15 or dialysis |

From Vellanki K. Pregnancy in chronic kidney disease. *Adv Chronic Kidney Dis.* 2013;20: 223–229.

2011). However, there are increased rates of IUGR, preterm birth, and preeclampsia. In those with severe renal impairment, there are increased rates of infertility, miscarriage, and poor perinatal outcome. These pregnancies are complicated by growth restriction (65%), preterm birth (90%), preeclampsia (60%), and perinatal death (10%) (Williams and Davison, 2008).

Ideally, patients with CKD should be seen prior to pregnancy. Preconception counseling regarding maternal and perinatal outcomes is dependent on the patient's baseline renal function, degree of hypertension, and various comorbid conditions. For example, those with severe renal impairment may be advised to consult with a nephrologist to determine whether medication therapy or dialysis should be considered. Implementing therapies that may optimize her medical status in the non-gravid state is recommended to improve outcome. Treatment with antihypertensive medications should be adjusted if necessary to reduce fetal consequences, particularly with the use of angiotensin-converting enzyme inhibitors or receptor blockers that are known teratogens. If the degree of renal impairment is unknown, a 24-hour urine for creatinine clearance and total proteinuria should be performed. Furthermore, screening for active renal processes such as glomerulonephritis, lupus nephritis, reflux, and infection is advisable, as treatment may improve the degree of renal dysfunction. Low-dose aspirin should be considered in early pregnancy to potentially reduce the rate of preeclampsia.

Management of pregnancy includes initial office visits every other week and then weekly after 32 weeks, as well as serial ultrasounds to evaluate fetal growth. The urine should be evaluated every 4–6 weeks for infection, proteinuria, and hematuria. The blood pressure targets should ideally be between 120/70 mmHg and 140/90 mmHg, making adjustments of antihypertensive medications as necessary. Maternal creatinine and hemoglobin levels are also regularly assessed, the frequency dependent on the patient's baseline renal dysfunction (Williams and Davison, 2008).

Cancer

Principles

Cancer complicating pregnancy is rare, with an estimated frequency of 1 case per 1000 live births. The trend of delaying childbearing to later maternal age and the increased rates of cancer in general have increased the incidence over the past four decades (Salani et al., 2014). The sites or types of cancer in pregnancy, in descending order of frequency, are cervical, breast, ovarian, lymphoma, melanoma, brain, and leukemia (Table 11.6) (Haas, 1984; Jacob and Stringer, 1990). Pregnancy probably complicates the diagnosis, given the overlap of symptoms, compromised physical examination, hesitation to obtain testing, and restrictions of imaging and biochemical markers. All of these factors may contribute to a delay in diagnosis.

Finding a malignancy during gestation poses a unique set of issues that must be addressed with care. Will the pregnancy accelerate the malignant process? Are the accepted therapies appropriate for the mother, and are they safe for the unborn fetus? Will delay of therapy adversely affect the mother? Should the pregnancy be terminated, or should the child be delivered prematurely to maximize treatment of the mother with no resultant risk to the child?

Few conditions in pregnancy require as meticulous and multidisciplinary approach as cancer. Providers unaccustomed to managing pregnant women may be reticent recommending definitive cancer therapy, for fear of the surgical or teratogenic risks to the

TABLE 11.6

Cancers That Can Complicate Pregnancy

| Site/Type | Incidence (Per Number of Gestations) |
|------------|--------------------------------------|
| Cervix | 1:2000–1:10,000 |
| Breast | 1:3000–1:10,000 |
| Melanoma | 1:1000–1:10,000 |
| Ovary | 1:10,000–1:100,000 |
| Colorectal | 1:13,000 |
| Leukemia | 1:75,000–1:100,000 |
| Lymphoma | 1:1000–1:6000 |

fetus. Therefore input regarding diagnosis and treatment must be acquired not only from an oncologist but also from the obstetrician, perinatologist, pediatrician, neonatologist, and dysmorphologist. The patient and her family must be involved in decision making. Information should include the risks of the disease and its potential therapies, as well as the limitations of current knowledge about cancer in pregnancy and any uncertainties of outcomes. Furthermore, depending on the gestational age at diagnosis, discussions regarding termination and potential iatrogenic prematurity are important.

In most cases, there should not be any delays in diagnostic procedures. As discussed previously, most imaging studies are relatively safe in pregnancy, but the exact modality can be modified to lessen the risk of fetal exposure, providing there is no reduction in an ability to make a diagnosis. Biopsies and indicated surgery should not be delayed for the sake of the pregnancy.

Chemotherapy

Administering agents that impair cell division in pregnancy is a concern for both the mother and the care team. Often the patient is more concerned about this issue than about the underlying cancer. Cytotoxic chemotherapy should be avoided in the first trimester because of the high incidence of spontaneous abortion and the potential teratogenic effects on the fetus. For a few agents with confirmed teratogenic effects (e.g., methotrexate, amethopterin, and chlorambucil), chemotherapy must be avoided during organogenesis. The use of folic acid antagonists in first-trimester cancer treatment raises the specific problem of possible induction of neural tube defects, because these lesions are known to be folate sensitive. For a list of the more common chemotherapeutic agents that have been used in pregnancy, refer to Table 11.7.

The literature regarding most chemotherapeutic agents is limited, consisting of a few collected series; therefore these agents should be used cautiously, with their potential harm to the fetus balanced against their benefit to the maternal condition. Little is also known regarding the long-term outcomes of fetuses exposed to chemotherapeutic agents in utero. The National Cancer Institute in Bethesda, Maryland, USA, maintains a registry in the hopes of determining the delayed effects. A small series of fetuses exposed to chemotherapeutic agents for acute leukemia revealed normal mental development with follow-up between 4 and 22 years (Aviles

TABLE 11.7 Common Chemotherapeutic Agents and Uses

| Class | Drug | Common Uses |
|--|----------------------------------|---|
| Alkylating Agents | | |
| Bind covalently to DNA, causing cross-links and strand breaks | Busulfan | Leukemias |
| | Chlorambucil | Lymphomas, leukemias |
| | Cyclophosphamide | Breast, ovary, lymphomas, leukemias |
| | Melphalan | Ovary, leukemia, myeloma |
| | Procarbazine | Lymphomas |
| Antimetabolites | | |
| Act as a false substrate during DNA and RNA synthesis, resulting in truncated proteins | 5-Fluorouracil | Breast, gastrointestinal |
| | 6-Mercaptopurine | Leukemias |
| | Methotrexate | Trophoblastic disease, lymphomas, leukemias, breast |
| | 6-Thioguanine | Leukemias |
| Antibiotics | | |
| Bind with DNA, prevent RNA synthesis, generate highly reactive free radicals | Bleomycin | Cervix, lymphomas |
| | Daunorubicin | Leukemias |
| | Doxorubicin | Leukemias, lymphomas, breast |
| Antimitotic Agents | | |
| Stop mitosis in M phase of cell cycle | Vincristine | Leukemias, lymphomas |
| | Vinblastine | Breast, lymphomas, choriocarcinomas |
| Taxanes | | |
| Inhibit disassembly of microtubules | Tamoxifen | Breast, lymphomas, choriocarcinoma |
| | Paclitaxel | Breast, ovarian |
| Platinum Compounds | | |
| Bind to DNA, causing cross-links and apoptosis | Cisplatin | Ovary, cervix, sarcoma |
| Other | | |

| | Hydroxyurea | Leukemias |
| | All- <i>trans</i> -retinoic acid | Leukemias |

Data from Neoplastic diseases. In Cunningham FG, MacDonald PC, Gant NF, et al., eds. *Williams Obstetrics*, ed. 20, Stamford, CT: Appleton and Lange; 1997; Ngu S, Ngan HY. Chemotherapy in pregnancy, *Best Pract Res Clin Obstet Gynaecol*. 2016;33:86–101.

and Niz, 1988). A recent case-control study involving 129 children, 96 of whom were exposed to chemotherapy in utero, suggested that maternal cancer with or without treatment did not impair cognitive, cardiac, or general development (Amant et al., 2015).

The risk of teratogenicity does not appear to be higher with combination chemotherapy than with single-agent therapy (Selig et al., 2012). Studies performed thus far involve small numbers of patients, with power insufficient to show a statistic difference, but there seems not to be a trend. There is an increased rate of small for gestational age babies and premature labor in mothers receiving cytotoxic chemotherapy (Van Calsteren et al., 2010). Theoretical consequences, such as bone marrow suppression, immune suppression, and anemia, could occur in the fetus. As a result, the timing of chemotherapy should account for the anticipated date of delivery. Data regarding safety for breastfeeding the neonate of

a mother receiving cancer chemotherapy are limited. For this reason, the majority of agents are contraindicated in nursing mothers.

Radiation Therapy

The deleterious effects of irradiation on the fetus have been discussed previously. Adjuvant radiation during pregnancy should be avoided if possible. However, there are small case series of radiotherapy in pregnancy, primarily for lymphoma (Eyre et al., 2015). There are several considerations for a pregnant woman undergoing radiation therapy. First, the dose used in estimating risk should be the amount that the fetus actually receives. For example, axillary or neck irradiation for lymphoma involves a lower direct fetal exposure than direct pelvic irradiation for cervical cancer. Secondly, the magnitude of radiation scatter to the pelvis must be considered. External

shielding does not prevent internal reflection of the ion beam. Thirdly, the advancing size of the uterus actually increases the amount of radiation exposure of the fetus, because of the closer proximity of the nonpelvic irradiation. Therefore an 8-week-old fetus may actually receive a smaller radiation dose from supraclavicular irradiation than a 30-week-old fetus. Fourthly, will the fetus concentrate the radiation and therefore increase its delivered dose? This is exemplified by the use of radioactive iodine (^{131}I) for maternal thyroid conditions. The actual rad dose is markedly higher in the fetus, because the fetal thyroid concentrates the iodine.

Cervical Cancer

Cervical cancer is one of the more common gynecologic malignancies in pregnancy. The incidence of cervical intraepithelial neoplasia is approximately 130 per 100,000 gestations and of invasive disease, 3.3 per 100,000 gestations (Al-Halal et al., 2013). A Papanicolaou test smear should be performed for all patients at their first prenatal visit and subsequent evaluation for an abnormal result should not be altered because of pregnancy. Colposcopy with cervical biopsy remains the mainstay of diagnosis. The greater vascularity of the cervix during pregnancy predisposes bleeding. An experienced colposcopist may be able to defer actual biopsy in cases of possible visual findings of a noninvasive process. However, if cancerous invasion is suspected, or if the physician is uncertain of the visual findings, biopsy is necessary. If microinvasive disease is confirmed by biopsy, cone biopsy is required to rule out frankly invasive disease. This procedure is undertaken with caution during pregnancy, because of the associated high rate of bleeding complications and miscarriage. Cervical conization may raise the risk of incompetence or preterm labor. The assistance of a gynecologic oncologist is preferred, given these unique sets of potential consequences. A shallow cone biopsy will reduce the risk of subsequent cervical weakness.

The therapy for invasive cervical cancer is based on the disease stage and gestational age as well as the patient's decision regarding pregnancy continuation and future fertility. Therapy can involve external beam radiation, internal radiotherapy (brachytherapy), or surgery. In most cases, delay of definitive therapy by 4–14 weeks may be acceptable. Pregnancy does not seem to accelerate the growth of the tumor. However, patient counseling is important. In the extremely previsible gestation, the likelihood of achieving a safe gestational age for the fetus without worsening the stage or spread of the cancer in the mother must be balanced against parental desires based on ethical or religious beliefs. Conversely, it might be reasonable to delay definitive therapy until a time when delivery would not likely result in a long-term disability because of extreme prematurity.

Breast Cancer

Breast cancer is the most common malignancy of women, with approximately 1 in 8 women affected in their lifetimes (Goldman and O'Hair, 2009): 0.2%–3.8% of cases are diagnosed during pregnancy (Vinatier et al., 2009). The incidence of breast cancer during pregnancy or within a year of delivery is 1.3 in 10,000 live births or 10–30 per 100,000 pregnancies (Isaacs, 1995; Smith et al., 2001a). Pregnancy does not seem to influence the actual course of the disease; however, there appears to be a higher risk of delay in diagnosis and a trend toward more advanced stages at diagnosis in pregnant, compared with nonpregnant, women.

The diagnostic procedures for breast cancer should not be altered during pregnancy. Any suspicious mass should undergo biopsy.

Mammography, although discouraged for routine screening in pregnancy, can be used safely if indicated. The fetal radiation exposure is negligible – approximately 0.001–0.01 mGy (Langer et al., 2015). Mammography may be more difficult to interpret due to the physiologic changes of pregnancy, and ultrasound examination may be a useful alternative. Metastatic evaluation may also be limited because of a reluctance to utilize bone and liver scans during pregnancy. MRI can be used safely in the second and third trimesters.

Surgical therapy for breast cancer should not be delayed because of pregnancy. The risks of mastectomy and axillary node dissection appear to be low (Isaacs, 1995). Radiation therapy is usually not recommended during pregnancy because of the risk of beam scatter to the pregnant uterus. If the pregnancy is to continue and the patient has evidence of tumor invasion in the lymph nodes, adjuvant chemotherapy is often given. The timing of delivery should account for the following factors:

- When would the fetus have a reasonable chance for survival with a low risk of severe permanent morbidity?
- Can the number of cycles of chemotherapy be minimized with an earlier delivery? In addition, avoiding delivery just before or just after administration of chemotherapy is important to reduce the risk of immunosuppression and infection.
- How long can radiotherapy be delayed without increasing the risk of metastatic spread of the tumor?

Approximately 10% of women treated for breast cancer become pregnant, the majority within 5 years of diagnosis. Data from small series suggest that pregnancy does not influence the rate of recurrences or of distal metastasis (Dow et al., 1994). While ideal timing of pregnancy after treatment for breast cancer is controversial, it seems reasonable to delay childbearing for at least 1–2 years, which is the time of the highest rate of recurrence (Landa et al., 2015). Breastfeeding may be possible in women who have undergone conservative breast cancer surgery.

Ovarian Cancer

Most ovarian cancer occurs in women older than 35 years. Delayed childbearing has been more widely accepted, exemplified by British birth rates doubling in women older than 30 years and tripling in women older than 40 years since 1975 (Palmer et al., 2009), in addition to a twofold increased birth rate among US women older than 40 years since 1981 (Martin et al., 2009). It would not be surprising for the rate of ovarian and other cancers during pregnancy to increase. However, the current estimate of actual ovarian malignancies in pregnancy is low and estimated to range from 1 in 10,000 to 1 in 50,000 deliveries (Palmer et al., 2009). Whereas most ovarian cancers are epithelial in origin, borderline epithelial and germ cell tumors (dysgerminomas and malignant teratomas) are more common in pregnancy.

The widespread use of ultrasonography, particularly in the first two trimesters, has been helpful in identifying adnexal masses. Fortunately, most are functional cysts (13%–17%) or benign teratomas, serous or mucinous cystadenomas, endometriomas, or paraovarian cysts (Hoover and Jenkins, 2011). Actual malignancy is rare and is estimated at 5% of the ovarian masses found. The risk is higher in nonpregnant females, approaching 15%–20%. Surgery for a suspected ovarian mass occurs in approximately 1 per 1000 pregnancies. Most procedures are performed not for suspected malignancy but because of concern about torsion and rupture. The incidence of adnexal torsion ranges from 1%–50%,

but more recent data suggest rates between 7% and 22% (Goh et al., 2014), and there appears to be a trend with increasing rates in masses greater than 6 cm (Yen et al., 2009). The maximal times of risk of these events are at the end of the first trimester, when the uterus elevates beyond the true pelvis, and at the time of delivery.

The characterization of an ovarian process can be aided by ultrasonography or MRI, but these modalities are not definitive. Ultrasound scoring systems that use size and character poorly predict malignancy but have a better negative predictive value (Lerner et al., 1994). Although an ovarian cyst, particularly if it is simple in nature, is probably not malignant, the patient must be cautioned that histologic diagnosis is more definitive. Indications for surgical exploration include a complex mass, a persistent simple cyst greater than 8 cm, or one that is symptomatic (Leiserowitz, 2006). The optimal time for laparotomy is during the second trimester. At that time, there is minimal interference from the gravid uterus and less risk of fetal loss, and the theoretical concerns of teratogenic exposure to anesthetic agents are avoided. Some patients opt for more conservative management; they should be counseled that they have a potential risk of requiring emergent surgery for an acute event such as torsion or rupture.

If a malignancy is confirmed at the time of laparotomy, treatment and staging are no different than for a nonpregnant woman. Frozen-section diagnosis, peritoneal washings, omentectomy, and sub-diaphragmatic biopsy are performed. Depending on the cell type and the stage, treatment can range from removal of the affected adnexa to complete hysterectomy and bilateral oophorectomy. Chemotherapy may be given during pregnancy if necessary. Fortunately, most epithelial ovarian cancers found in pregnant women are usually of a lower stage, with 59% of reported cases being stage I (Palmer et al., 2009).

Survivors of Childhood Cancer

Given the improvements of therapy for childhood cancer, a large number of these individuals have survived into adulthood. Some are unable to conceive because of high-dose radiation or cytotoxic chemotherapy. The risk of decreased fertility for patients exposed to pelvic radiation therapy may as high as 32% (Georgesescu et al., 2008). Those who remain fertile may have concerns regarding whether their treatment increases the risk of adverse pregnancy outcomes. Although data are limited, female cancer survivors treated with radiation therapy appear to have increased risks of premature delivery, low birth weight, and miscarriage. There is no evidence that female partners of male cancer survivors treated with radiation have these excess risks (Reulen et al., 2009).

Maternal Seizure Disorders

Epilepsy is the most common major neurologic disorder in pregnancy. Approximately 18 million women are affected worldwide, and 40% of those are of childbearing age. The estimated prevalence in pregnancy is 0.2%–0.7% (Chen et al., 2009). The pattern of maternal seizures ranges from complex partial to generalized tonic-clonic (grand mal) and generalized absence (petit mal) seizures. Physiologically, seizures arise from paroxysmal episodes of abnormal brain electrical discharges; when associated with motor activity, they are termed convulsive.

The effect of pregnancy on the frequency and severity of the seizure disorder has been difficult to ascertain because of limited prospective data. EURAP, an international registry of Antiepileptic Drugs and Pregnancy, recently reported on more than 1800 patients

whose seizure frequency and treatment were recorded. Fifty-eight percent of patients had no seizures during their pregnancy. When using first-trimester seizure activity as a reference, 64% had no change in frequency in the second and third trimester, 6% improved, and 12% deteriorated (EURAP Study Group, 2006). The only exception was that tonic-clonic seizures occurred more frequently in women using oxcarbazepine monotherapy; this has been confirmed by an Australian registry in which seizures occurred in 50% of pregnant women with epilepsy who were receiving therapy. However, in a subset that had no seizures for 12 months before pregnancy, there was a 50%–70% reduced frequency during gestation (Vajda et al., 2008). In patients in whom higher numbers of seizures occur during gestation, decreased plasma concentrations of antiepileptic medications have been hypothesized as causative. The fall in plasma drug levels during pregnancy may be due in part to increased protein binding, reduced absorption, and increased drug clearance. The adequacy of prepregnancy seizure control can influence a patient's course during gestation. Patients whose seizures were poorly controlled tended to have more frequent seizures during pregnancy, whereas patients who had no seizures for 2 years before pregnancy had only a 10% chance of experiencing seizures during gestation. These latter patients may be candidates for stopping therapy or considering monotherapy if they have previously required multiple antiepileptic drugs (Schmidt et al., 1983; Walker et al., 2009).

Perinatal Risk

For reasons that are not clear, women with seizures have more obstetric complications and a higher rate of poor perinatal outcomes. A recent systematic review comparing women with epilepsy to those without revealed increased odds of spontaneous miscarriage, antepartum and postpartum hemorrhage, hypertensive disorders, labor induction, cesarean section, preterm birth, and fetal growth restriction (Viale et al., 2015).

Earlier publications suggested an increased risk of congenital malformations in children of mothers with epilepsy even without prenatal use of antiepileptic drugs. More recent data appear to refute this. A study comparing patients with epilepsy to matched controls revealed that women receiving no medication had no increased rate of congenital malformations; however, monotherapy was associated with an increased risk of embryopathy (odds ratio [OR] 2.8). Furthermore, the frequency was even higher with use of two or more drugs (OR 4.2) (Holmes et al., 2001). A metaanalysis revealed the OR of malformations in those with untreated epilepsy was similar to nonepileptic controls (OR 1.92, 95% confidence interval [CI] 0.92–4) but a higher prevalence of a major congenital malformation in those exposed to antiepileptic medications (OR 3.26, 95% CI 2.15–4.93) (Fried et al., 2004). The malformation risk correlates with the number of medications used and is dose dependent in those receiving monotherapy (Tomson et al., 2011). Recent updates from five international registries have reported malformation rates ranging from 3.7%–8.0% (with monotherapy) and 6%–9.8% (with polytherapy) (Meador et al., 2008). Specific malformations associated with antiepileptic medications include a fivefold rise in the rate of orofacial clefts (Friis et al., 1986), an increase in the rate of congenital heart disease, particularly with trimethadione (Friis and Hauge, 1985), and a 3.8% incidence of neural tube defects in fetuses exposed to valproic acid (Samrén et al., 1997). Facial abnormalities (e.g., midface hypoplasia) are not specific to any particular antiepileptic drug; they have been seen with phenytoin, carbamazepine, and trimethadione. Some antiepileptic medications can adversely affect postnatal cognitive

TABLE 11.8 Clinical Features of the Fetal Hydantoin Syndrome

development. Although conclusive data are lacking, there may be an increased adverse effect, particularly with valproate (Meador et al., 2008; Tomson and Battino, 2009).

Fetal Hydantoin Syndrome

The classic features of the fetal hydantoin syndrome are facial clefting, a broad nasal ridge, hypertelorism, epicanthal folds, distal phalangeal hypoplasia, and growth and mental deficiencies; however, these effects also result from the use of other antiseizure medications (Table 11.8). The postulated cause of this syndrome is the teratogenic action of a common epoxide intermediate of these medications. The hydantoin syndrome was found to develop in fetuses with inadequate epoxide hydrolase activity (Buehler et al., 1990). This enzymatic deficiency appears to be recessively inherited. It appears that preconception folic acid supplementation can reduce the risk of major congenital malformations in women taking antiepileptic medication (Harden et al., 2009).

Management

Management of the pregnant patient with epilepsy is based on keeping her free of seizures. Theoretically, this goal reduces maternal physical risk and lowers the incidence of fetal complications. Preconception counseling is preferable and should entail (1) adjusting medication doses into the therapeutic range, (2) attempting to limit the patient to one drug if possible, and (3) choosing an agent with the least risk of teratogenesis. Frank discussion of the various risks of each agent should be conducted, particularly the risks associated with valproic acid and trimethadione. Usually if the patient's disease is adequately controlled with one agent, it rarely needs to be changed, because the risks of increasing seizure activity are believed to outweigh the potential for reducing congenital malformations.

Patients taking antiepileptic medications should also take folic acid supplements (800–1000 µg) before conception, because

inhibition of folate absorption has been proposed as a teratogenic mechanism, particularly with phenytoin. However, there is some controversy about the use of higher doses of folic acid, as there is some evidence of potential drug–drug interactions and animal evidence that high levels may have adverse effects on fetal brain development (Asadi-Pooya, 2015). Maternal serum screening for neural tube defects, fetal ultrasound, and echocardiography should be performed in the mid-trimester. During gestation, the anticonvulsant levels should be checked monthly, and the dose should be adjusted accordingly, particularly with the use of lamotrigine, carbamazepine, and phenytoin (Harden et al., 2009). Although the evidence is less clear with other agents such as phenobarbital, valproate, primidone, and ethosuximide, serial level assessment should not be discouraged. Medications should not be changed unless they prove ineffective at the optimal serum level. If a patient reports greater seizure activity, the serum drug level should be checked immediately. A common reason for increased seizures is that the patient is not taking her medication, usually because she fears its teratogenicity.

Mothers taking phenytoin, phenobarbital, or primidone may have a higher incidence of neonatal coagulopathy as a result of vitamin K-dependent clotting factor deficiency. Although maternal vitamin K supplementation in the third trimester may be reasonable, there is insufficient evidence to determine whether it will reduce neonatal hemorrhagic complications (Harden et al., 2009).

Mental Health Disorders

It is estimated that, annually, over 500,000 pregnancies are complicated by maternal mental health disorders (ACOG, 2008). If inadequately recognized or treated, patients may be at increased risk of poor nutrition; maladaptive behaviors such as smoking, drinking, and illicit drug use; poor compliance with medical care; and deficits of mother–child bonding. Furthermore, there appears to be an increased perinatal risk with mental disorders and pregnancy (Table 11.9). Women with preexisting mental illness have a higher recurrence risk in the puerperium. Patients with suspected mental illness should also be assessed for substance abuse and thyroid dysfunction. A multidisciplinary approach is advantageous. In rare cases, the patient's mental competency is an issue, which may require legal assistance to determine who may make medical decisions for the patient.

Depression

Depression ranks as the fourth leading cause of disability worldwide, and recognized prevalence appears to be increasing (Dossett, 2008). Rates of depression during pregnancy are 7%–11% in the first trimester, 9%–13% in the second trimester, and 9%–12% in the third trimester (Bennett et al., 2004; Gavin et al., 2005). The prevalence over the entire pregnancy course is 18.4% (Gavin et al., 2005). The obstetrician must be aware that life events such as miscarriage, infertility, and complicated pregnancy in patients with risk factors are likely to precipitate depression; therefore there should be a low threshold for diagnosis and treatment of mood alterations in such patients. Alternatively, perinatal loss experienced by a woman without predisposing risk factors will probably lead to a grief reaction or adjustment disorder, which may be misdiagnosed as depression.

Chronic medical conditions that are associated with a high prevalence of depression and may occur in women of childbearing age include renal failure, cancer, AIDS, and chronic fatigue or pain. Antihypertensives, hormones, anticonvulsants, steroids,

TABLE 11.9 Impact of Psychiatric Illness on Pregnancy Outcome

| Illness | Teratogenic Effects | IMPACT ON OUTCOME | | Treatment Options |
|-------------------|---|---|---|---|
| | | Obstetric | Neonatal | |
| Anxiety disorders | N/A | Increased incidence of forceps deliveries, prolonged labor, precipitate labor, fetal distress, preterm delivery, and spontaneous abortion | Decreased developmental scores and inadaptability; slowed mental development at 2 years of age | Benzodiazepines Antidepressants Psychotherapy |
| Major depression | N/A | Increased incidence of low birth weight, decreased fetal growth, and postnatal complication | Increased newborn cortisol and catecholamine levels, infant crying, rates of admission to NICUs | Antidepressants Psychotherapy ECT |
| Bipolar disorder | N/A | Increased incidence of low birth weight, decreased fetal growth, and postnatal complication | Increased newborn cortisol and catecholamine levels, infant crying, rates of admission to NICUs | Lithium Anticonvulsants Antipsychotics ECT |
| Schizophrenia | Congenital malformations, especially cardiovascular | Increased incidence of preterm delivery, low birth weight, small for gestational age, placental abnormalities, and placental hemorrhage | Increased rates of postnatal death | Antipsychotics |

ECT, Electroconvulsive therapy; N/A, not applicable; NICUs, neonatal intensive care units.

From ACOG Committee on Practice Bulletins—Obstetrics. ACOG Practice Bulletin. Clinical management guidelines for obstetrician-gynecologists number 92, April 2008 (replaces practice bulletin number 87, November 2007). Use of psychiatric medications during pregnancy and lactation, *Obstet Gynecol.* 2008;111:1001–1020.

chemotherapeutics, and antibiotics can cause depression. Alcoholism and substance abuse may manifest as depression. Underlying personality disorders complicate the diagnosis of depression by confusing the clinical presentation, in addition to contributing to the secondary effect of many physicians' avoidance of patients suffering from such disorders.

Supportive therapy alone is rarely effective for major depression. Therapeutic interventions include psychotherapy and medication. Electroconvulsive therapy (ECT) has been used in pregnancy, usually for refractory severe cases of psychotic depression, schizophrenia, and bipolar disease. There are some potential complications with ECT, including fetal bradycardia (2.7%), preterm contractions, or labor (3.5%), and potential complications of anesthesia including aspiration (Anderson et al., 2009).

Medication is by far the most common treatment modality. However, it is associated with concerns about fetal exposure, leading patients or providers to limit or discontinue medication use. Unfortunately those who discontinue antidepressants before pregnancy have a 68% risk of relapse as opposed to a 26% risk in those whose medication was maintained. In those who discontinued medication and suffered a relapse, 50% did so in the first trimester and 90% by the second trimester (Cohen et al., 2006). Another study found that among those who discontinued antidepressants, over half had to restart them in pregnancy (Roca et al., 2013).

The maternal risk of depression can be significant, including an increased risk of suicidal ideation (Einarson et al., 2001). Therefore careful assessment regarding the need for medication, counseling regarding the risks of medication discontinuation versus the potential concerns regarding the fetal impact of their use, and ongoing evaluation of patients during pregnancy are paramount.

In general, treatment of depression is effective in approximately 70% of cases. Most antidepressant medications currently prescribed during pregnancy are selective serotonin reuptake inhibitors (SSRIs), which have an advantage over the tricyclic antidepressants by not

causing orthostatic hypotension. While they are commonly used in pregnancy, complications of fetal exposure have not been fully established. SSRIs as a group have not been consistently associated with specific birth defects (Byatt et al., 2013). However, paroxetine has been associated with a small but increased risk of congenital heart defects (Källén and Otterblad Olausson, 2007; Grigoriadis et al., 2013). Although data remain inconsistent, current recommendations are to avoid paroxetine as a first-line antidepressant.

One concern regarding the use of SSRIs is the association with persistent pulmonary hypertension of the newborn (PPHN); however, the incidence remains low, at approximately 10 in 1000 fetuses exposed after 20 weeks' gestation (Chambers et al., 2006). This study was one of the first to link SSRIs to potential newborn harm. In five subsequent studies, two studies have found a small but statistically increased risk, but three studies did not (Robinson, 2015). In reviewing the potential relationship between SSRI and PPHN, there are a number of risk factors for this disorder that are more commonly seen in depressed women, including obesity, smoking, cesarean section, and early delivery (Occhiogrosso et al., 2012). Other controversies regarding SSRIs and their link to prematurity and low birth weight when systematically evaluated suggest that the medication is not the most likely cause but, rather, the underlying depression.

Approximately 30% of newborns exposed to SSRIs prior to birth develop poor neonatal adaptation syndrome (PNAS) (Weiskopf et al., 2015). This is usually transient and most often does not require specific medical care. PNAS affects the central nervous system, motor function, and the gastrointestinal and respiratory systems. NICU admissions are more common (Lund et al., 2009). Reduction of medication dose in the latter third trimester in the hope of reducing adverse neonatal outcomes does not appear to be beneficial (Warburton et al., 2010). Long-term outcome data suggest that maternal antidepressants do not cause autism or affect the neurodevelopment of offspring (Robinson, 2015). Therefore given the lack of consistent data suggesting significant fetal harm,

SSRIs are currently considered the first-line antidepressant for use in pregnancy (Weisskopf et al., 2015). Furthermore, reducing the dose or discontinuing SSRIs in the latter part of pregnancy does not appear to improve neonatal outcome.

There have been concerns regarding the use of SSRIs during breastfeeding. Fluoxetine has an active metabolite with a long half-life and is found in higher concentrations in infants (Eberhard-Gran et al., 2006). Short-term neonatal effects have been reported, including increased crying, decreased sleep, and irritability, particularly with fluoxetine and citalopram. However, the relative infant dose ingested by the child is less than 10% of the maternal dose, and this level is lower than the fetal exposure (Weisskopf et al., 2015). In some cases such as prematurity, where there is immaturity of drug elimination pathways, there may be potential for “toxicity” (irritability, agitation, sleep disturbances, etc.). However, this is usually reversible with breastfeeding discontinuation. There are clear benefits of breastfeeding that must be accounted for in decisions regarding those needing SSRIs, particularly at the highest time of maternal risk. The current available data do not support a contraindication for lactation (Weisskopf et al., 2015).

Postpartum Psychosis

A severe disorder, postpartum psychosis, is fortunately rare, occurring in 1–4 per 1000 births (Weissman and Olfson, 1995). This condition is more worrisome than postpartum depression, because of the patient’s inability to discern reality from the periods of delirium. Patients at risk for postpartum psychosis may have underlying depression, mania, or schizophrenia. Other risks are younger age and family history. The recurrence rate is approximately 25%. The peak onset of symptoms is between 10 and 14 days after delivery. Recognition of this disorder is extremely important to the protection of the patient and her family.

Schizophrenia

The prevalence of schizophrenia is approximately 1% in the general population (Myers et al., 1984); it is associated with delusions, hallucinations, and incoherence. Morbidity due to this mental illness is higher than that due to any other. There appears to be a genetic component to the etiology; schizophrenia develops in approximately 10% of offspring of an affected person. Concordance of schizophrenia in identical twins reaches 65%. There is some speculation and controversy as to whether low birth weight (Smith et al., 2001b) and obstetric complications (Kendell et al., 2000) are associated with a higher rate of schizophrenia.

Because the peak age of incidence is approximately 20 years and women are affected more often than men, it is unrealistic to assume that obstetricians will never encounter patients with schizophrenia. There appear to be higher rates of cesarean section and surgical vaginal delivery in affected patients (Bennedsen et al., 2001a). Offspring of women with schizophrenia may have a higher rate of sudden infant death syndrome and congenital malformations (Bennedsen et al., 2001b). However, it is difficult to ascertain whether these risks are independent of other factors such as smoking, poor socioeconomic status, and use of certain medications.

Treatment is achieved primarily through the use of psychotropic medication. The potential for teratogenesis appears low with the older-generation medications in the phenothiazine class, but most data for this issue were derived from the use of lower doses given to patients with hyperemesis gravidarum. Antipsychotic medication does cross the placenta. Current recommendations include avoiding use in the first trimester if possible, the use of lower doses or higher-potency alternatives, and cessation of medication 5–10 days before delivery (Herz et al., 2000). The use of most antipsychotics in breastfeeding is associated with an unknown risk (Briggs et al., 2005) (Table 11.10).

TABLE 11.10 Summary of Current Knowledge of Drug Excretion Into Breast Milk, Drug Concentrations in Infant Serum, Adverse Effects in the Child, and Breastfeeding Recommendations for Different Psychotropic Drugs

| Class or Drug | Drug Transfer Into Breast Milk | Infant Plasma Concentrations | Adverse Effects in the Child | Breastfeeding Recommendations |
|---------------------------------|--------------------------------|---|---|--|
| SSRIs | Low transfer | Low plasma concentrations | Case reports of adverse effects in infants exposed to fluoxetine and citalopram | Compatible with breastfeeding; however, fluoxetine and citalopram may not be drugs of first choice |
| TCAs | Low transfer | Low plasma concentrations (except doxepin) | No suspected immediate adverse effects observed (except doxepin) | Compatible with breastfeeding; however, doxepin should be avoided |
| Other antidepressants | Limited data | Limited data | Limited data | Insufficient data |
| Benzodiazepines | Low transfer | High plasma concentrations with longer-acting drugs with active metabolites | Case reports of CNS depression reported for diazepam | Sporadic use of short-acting benzodiazepines unlikely to cause adverse effects |
| Lithium | Low transfer | Dose received by the infant is high | Limited data; some reports of toxicity in the infant | Limited data; however, breastfeeding should be avoided |
| Carbamazepine, sodium valproate | Low transfer | Low plasma concentrations | Some case reports of various adverse effects in the infant | Generally more compatible with breastfeeding than lithium |
| Lamotrigine | High transfer | High plasma concentrations | Limited data | None able to be made |
| Novel antipsychotics | Moderate transfer | Variable plasma concentrations | Limited data | None able to be made |

CNS, Central nervous system; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

Modified from Eberhard-Gran M, Eskild A, Opjordsmoen S. Use of psychotropic medications in treating mood disorders during lactation: practical recommendations. *CNS Drugs*. 2006;20:187–198.

Lithium, used primarily in mania, is associated with a higher rate of Ebstein anomaly. Although the incidence of this consequence is low, either discontinuing the medication in the first trimester or continuing its use with careful counseling is a viable alternative. Fetal echocardiography should be performed in women who have used lithium in early pregnancy.

Hypertensive Complications of Pregnancy

THOMAS R. MOORE

KEY POINTS

- Hypertensive disorders of pregnancy are classified as chronic hypertension, gestational hypertension, preeclampsia (PE) with and without severe features, and chronic hypertension with superimposed PE.
- Pharmacologic management of chronic hypertension should be reserved for women with sustained elevations in blood pressure at or above 160 mmHg systolic or 110 mmHg diastolic.
- Magnesium sulfate administration to prevent eclampsia is used for those PE cases with severe features.
- Delivery in cases of PE without severe features should be accomplished at or beyond 37 completed gestational weeks. When severe features are present, delivery should be accomplished expeditiously (regardless of gestational age) once maternal stabilization has been achieved.

Hypertension is the most common medical problem in pregnancy, affecting 10%–15% of all pregnant women. As the third most common cause of maternal mortality after thromboembolic disease (15%) and hemorrhage (11%), hypertensive disorders account for almost 10% of maternal deaths in the United States (Creanga et al., 2015). Complications arising from hypertensive disorders have profound effects on the fetus and neonate and thus are a major source of perinatal mortality and morbidity. Preeclampsia (PE) is a leading cause of maternal and perinatal morbidity and mortality, with an estimated 50,000–60,000 PE-related deaths per year worldwide.

Unfortunately the incidence of PE has increased by 25% in the United States during the past two decades (Shih et al., 2016). Furthermore, since PE has been shown to be a risk factor for future cardiovascular and metabolic disease in women, the importance of proper perinatal management and, ideally, prevention has never been more important (Behrens et al., 2016).

Classification of Hypertensive Disorders of Pregnancy

The diagnostic criteria for the hypertensive complications of pregnancy have undergone significant revision in the past several

years (ACOG, 2002; Lindheimer et al., 2010; WHO, 2011; Magee et al., 2014). In 2013, the American College of Obstetricians and Gynecologists (ACOG) convened a Task Force to summarize the current state of knowledge about PE and other hypertensive disorders in pregnancy and to translate this information into practice guidelines (ACOG, 2013). Hypertension during pregnancy was defined by four categories (Table 12.1):

1. Chronic hypertension predating pregnancy
2. Gestational hypertension (GH) occurring after 12 weeks' pregnancy
3. Preeclampsia–eclampsia
4. Chronic hypertension with superimposed PE

Importantly, proteinuria is no longer required for the diagnosis of PE if other abnormal findings are present. PE is now defined as hypertension plus proteinuria *or* hypertension plus other systemic abnormalities:

Hypertension in pregnancy is defined when blood pressure is:

- Greater than 140 mmHg systolic or greater than or equal to 90 mmHg diastolic on two occasions at least 4 hours apart after 20 weeks' gestation in a woman with a previously normal blood pressure. The requirement for documenting hypertension twice over an interval of at least 4 hours is shortened to minutes if systolic pressure is greater than or equal to 160 mmHg or diastolic pressure is greater than equal to 110 mmHg.

Proteinuria is defined when urine studies show:

- Greater than or equal to 300 mg per 24-hour urine collection *or*
- Protein/creatinine ratio greater than or equal to 0.3 *or*
- Dipstick reading of 1+ in a voided urine specimen if more precise laboratory-based results are not readily available

In the presence of hypertension but absent proteinuria, PE is diagnosed when any of the following are present:

- Platelet count less than 100,000/ μ L.
- Elevated liver transaminase levels to twice normal values
- Newly elevated serum creatinine greater than 1.1 mg/dL or a doubling in the absence of other renal disease
- Pulmonary edema *or*
- New-onset cerebral or visual disturbances

Since fetal growth restriction is managed similarly in pregnant women with and without PE, it has been deleted as a criterion for severe PE.

TABLE 12.1 Classification of Hypertensive Disorders of Pregnancy

| Category | Definition |
|---|---|
| Chronic hypertension | Hypertension present before pregnancy or diagnosed before 20 weeks' gestation. Hypertension is defined as either systolic BP of ≥ 140 mmHg or diastolic BP of ≥ 90 mmHg or both. Diagnosis optimally should be based on two observations at least 4 hours apart, although with severe BP elevations shorter intervals may suffice. |
| Gestational hypertension | New-onset hypertension after 20 weeks' gestation in the absence of proteinuria that normalizes postpartum Change diagnosis to chronic hypertension if blood pressure elevation does not resolve after delivery. |
| Preeclampsia–eclampsia | New-onset hypertension (usually after 20 weeks' gestation) with new-onset proteinuria (300 mg/24 hours or a protein/creatinine ratio of at least 0.3) or one or more of the following: <ul style="list-style-type: none"> – thrombocytopenia ($<100,000/\mu\text{L}$) – elevated liver transaminases (twice normal) – renal insufficiency (serum creatinine >1.1 mg/dL or doubling creatinine level without preexisting renal disease) – pulmonary edema – new-onset cerebral or visual disturbances |
| Chronic hypertension with superimposed preeclampsia | Preeclampsia occurring in a woman with hypertension predating pregnancy |

BP, Blood pressure.

Data from American College of Obstetricians and Gynecologists. Hypertension in Pregnancy. Washington, DC: American College of Obstetricians and Gynecologists; 2013.

Chronic Hypertension

Up to 5% of pregnant women have chronic hypertension, which is diagnosed when hypertension is present before pregnancy or recorded before 20 weeks' gestation. However, when hypertension is first noted in a patient after 20 weeks' gestation, it may be difficult to distinguish chronic hypertension from pregnancy-induced hypertension or PE. In such cases, the precise diagnosis might not be made until after delivery. Hypertension that is first diagnosed during the second half of pregnancy and persists postpartum is diagnosed as chronic hypertension.

Chronic hypertension has an adverse effect on pregnancy outcome. A recent summary of 55 studies of women with chronic hypertension, encompassing 795,221 pregnancies, indicated that women with chronic hypertension had pooled incidences of superimposed PE (25.9%), cesarean section (41.4%), preterm delivery at less than 37 weeks' gestation (28.1%), birth weight less than 2500 g (16.9%), neonatal unit admission (20.5%), and perinatal death (4.0%) (Bramham et al., 2014). The adverse effects on fetal

and maternal perinatal outcomes are related to the severity of the preexisting hypertension. When chronic hypertension is secondary to maternal chronic renal disease, a large (506,000 pregnancies) systematic review found significantly elevated odds of PE (odds ratio [OR] 10.36), premature delivery (OR 5.72), small for gestational age (OR 4.85), and pregnancy failure (OR 1.80) (Zhang et al., 2015). Women with untreated severe chronic hypertension are also at increased risk for cardiovascular complications during pregnancy, including stroke (Brown and Whitworth, 1999).

The majority of cases of chronic hypertension seen in pregnancy are idiopathic (essential hypertension), but causes of secondary hypertension should always be sought because pregnancy outcome is worse in women with secondary hypertension. Renal disease (e.g., chronic renal failure, glomerulonephritis, renal artery stenosis), cardiovascular causes (coarctation of the aorta, Takayasu arteritis), and, rarely, Cushing disease, Conn syndrome, and pheochromocytoma should be excluded through physical examination, history, and more detailed testing if needed.

All patients with chronic hypertension should be evaluated early in pregnancy with serum urea, creatinine, and electrolyte measurements, urinalysis, and 24-hour urine collection for protein and creatinine clearance determinations. Reassessment should be performed in each trimester and more frequently if the patient's condition deteriorates.

Antihypertensive Treatment of Chronic Hypertension in Pregnancy

Randomized trials have shown that antihypertensive treatment of chronic hypertension in pregnancy does not improve fetal outcome (ACOG, 2013), with rates of preterm delivery, abruption, intra-uterine growth restriction (IUGR), and perinatal death similar in treated and untreated women. Therefore treatment is usually reserved for patients whose hypertension places them at a significant risk of maternal stroke (systolic blood pressure of ≥ 160 mmHg or diastolic pressure of ≥ 110 mmHg). In patients with less severe hypertension who were taking medications before conception, discontinuing therapy with close surveillance is recommended. The risk of superimposed PE is not changed by antihypertensive therapy, so its development should be tracked carefully.

The choice of antihypertensive agent for use in pregnancy is governed by avoiding adverse effects on the fetus. Because excessive lowering of maternal blood pressure to less than 140 mmHg systolic or less than or equal to 90 mmHg diastolic (140/90 mmHg) can compromise uterine perfusion, with consequent slowing of fetal growth with ultimate reduction in fetal oxygenation, maternal pressures should be maintained in the 140–155 mmHg systolic and 90–105 mmHg diastolic range. The drugs most commonly used in pregnancy are listed in Table 12.2.

Labetalol is a mixed α_1 -adrenergic, β_1 -adrenergic, and β_2 -adrenergic blocker, and it is the most frequently used medication. Some pure β -blockers have been associated with a significant increase in the risk of IUGR (e.g., atenolol), and the mixed adrenergic blockade produced by labetalol is thought to mitigate this unwanted effect (Pickles et al., 1989). Labetalol is also used intravenously to manage severe hypertension accompanying PE.

Methyldopa, a centrally acting antihypertensive agent, does not impair uteroplacental perfusion and has a wide therapeutic margin. However, methyldopa has a rather slow onset of action, with prolonged time to therapeutic effect (days), and compliance with methyldopa therapy may be impeded by side effects such as sedation in some patients.

TABLE 12.2 Drugs Commonly Used to Treat Chronic Hypertension in Pregnancy and Their Modes of Action

| Drug | Mode of Action | Typical Dose |
|------------|---|--------------------------------------|
| Methyldopa | Centrally acting antihypertensive | 0.5–3 g/day in 2–3 divided doses |
| Labetalol | Mixed α -adrenergic and β -adrenergic blockers | 200–2400 mg/day in 2–3 divided doses |
| Nifedipine | Calcium channel blocker | 30–120 mg/day in slow-release form |

Adapted from American College of Obstetricians and Gynecologists; Task Force on Hypertension in Pregnancy. Hypertension in pregnancy. Report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy. *Obstet Gynecol.* 2013;122:1122–1131.

Calcium channel blockers (e.g., nifedipine) have been used mainly as second-line drugs, usually in long-acting, extended-release forms. Calcium channel blockers appear to be as effective as methyldopa and labetalol with minimal fetal side effects (Levin et al., 1994).

Hydralazine, a potent peripheral vasodilator, is frequently used intravenously to treat acute hypertensive emergencies in pregnancy (blood pressure >160/110 mmHg). Its role as an oral agent in the management of chronic hypertension is limited to a second or third-line choice. Long-term use of hydralazine may be associated with a lupus-like syndrome in some patients.

Although diuretics are used extensively in nonpregnant adults with hypertension, there is little role for their use in women with chronic hypertension in pregnancy. Diuretics can potentially reduce or prevent the plasma volume expansion seen in normal pregnancy (Sibai et al., 1984), an effect that might impede fetal growth, although the evidence for this is mixed. Most authorities restrict the use of diuretics in pregnant patients to those with cardiac dysfunction or pulmonary edema.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers should not be used during pregnancy. In the second and third trimesters, these agents are associated with malformation of the fetal calvarium, fetal renal failure, oligohydramnios, pulmonary hypoplasia, and fetal and neonatal death (Buttar, 1997). Angiotensin-converting enzyme inhibitors appear to be safe when taken in the first trimester (Steffensen et al., 1998), but a patient who conceives while taking an angiotensin receptor blocker or angiotensin-converting enzyme inhibitor should be switched to a safer alternative as soon as possible. Similar precautions apply to the use of angiotensin receptor blockers in pregnancy.

Antenatal Fetal Surveillance in Chronic Hypertension

As women with chronic hypertension are at increased risk of slowing of fetal growth and of superimposed PE, antenatal surveillance in women with chronic hypertension should include careful screening for signs of superimposed PE and serial ultrasonographic evaluations every 3–6 weeks. All patients should perform fetal movement counts from 28 weeks' gestation onward, and cases with slowing of fetal growth should be followed with twice-weekly nonstress tests with amniotic fluid index or a weekly ultrasound biophysical profile.

• BOX 12.1 Management of Pregnant Women With Chronic Hypertension

Monitoring

- Daily home BP monitoring
- Fetal growth sonography every 4 weeks
- Fetal biophysical testing at least weekly from 32–34 weeks

Avoid

- Low sodium diets
- Weight loss prescriptions
- Limitations of moderate exercise

Prophylaxis

If prior pregnancy had PE with severe features and delivery was <34 0/7 weeks, begin daily low-dose aspirin (81 mg) by 15 weeks' gestation.

Antihypertensive Medications

- Maintain systolic BP 120–160 mmHg; diastolic BP 80–105 mmHg
- Utilize labetalol, nifedipine, or methyldopa if antihypertensives needed
- Avoid ACE inhibitors, ARBs, renin inhibitors, and mineralocorticoid receptor antagonists.

Delivery

- At 37 0/7 weeks unless PE with severe features
- If <37 0/7 weeks, administer antenatal corticosteroids
- If PE with severe features
 - Soon after maternal stabilization if uncontrollable BP, eclampsia, pulmonary edema, abruptio placentae, nonreassuring fetal status
 - Administer antepartum and postpartum magnesium sulfate.

ACE, Angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; BP, blood pressure; PE, preeclampsia.

If the sonographic estimated fetal weight tapers below the 10th percentile or abdominal circumference is a much smaller percentile than the head, more intensive fetal surveillance is indicated and IUGR is diagnosed. In such cases, sonography should be performed at 10-day to 21-day intervals with attention paid to amniotic fluid volume and trending of each biometric parameter. Serial monitoring of umbilical Doppler waveforms in IUGR has been shown to reduce perinatal mortality while not increasing labor induction or cesarean delivery (ACOG, 2013). Indications for delivery in the hypertensive patient with fetal IUGR include absence of growth of the head and abdomen over a 10-day interval, oligohydramnios, biophysical score of less than 6, or reversal of end-diastolic velocity on the umbilical Doppler waveform.

Women with renal impairment and chronic hypertension have a markedly higher risk of poor perinatal outcome than women without renal impairment. The incidence of impaired fetal growth is directly related to the degree of renal impairment, and women undergoing dialysis are at particular risk for fetal growth failure, preterm delivery, and fetal death, even with optimal management. Those who start dialysis during pregnancy are at the greatest risk, with only a 50% chance of a surviving infant (Hou, 1999).

Gestational Hypertension

Management of women with GH and PE is summarized in Box 12.1. GH is defined as new-onset hypertension occurring after 20 weeks' pregnancy in the absence of signs of PE. Because a woman with apparent GH at 36 weeks' gestation can rapidly evolve into

PE at 39 weeks' gestation, the diagnosis of GH should always evoke caution and vigilance. Only if the patient's blood pressure returns to normal postpartum, without development of signs of PE during the pregnancy, should the final diagnosis of GH be applied. During pregnancy, GH is indistinguishable from preeclampsia-in-evolution. Therefore all patients with GH should be regarded as being at risk for progression to PE.

The earlier that GH is evident, the greater the risk of PE. When the diagnosis is made before 30 weeks' gestation, more than one-third of patients will develop PE, whereas the risk is less than 10% when the diagnosis is made after 38 weeks' gestation. Use of antihypertensive agents to treat patients with GH should be avoided, given the risk of concurrent PE and the lack of evidence supporting improved fetal outcome. GH tends to recur in subsequent pregnancies and predisposes women to hypertension in the future (Marin et al., 2000).

Preeclampsia–Eclampsia

Apparently unique to humans, the underlying causes of PE remain poorly elucidated. It is evident that the clinical manifestations of PE arise from vascular endothelial dysfunction that ultimately involves the central nervous, renal, hepatic, and cardiovascular systems. In its full-blown form, PE can produce a profound coagulopathy and liver, respiratory, or cardiac failure and maternal death.

PE is categorized as having severe features when systemic complications (e.g., renal, hepatic, pulmonary, or hematologic) are present (Box 12.2). This distinction is important, because when the presence of severe features is documented at any gestational age, the only appropriate treatment option is delivery, whereas expectant management may be acceptable in a woman who has mild disease and is remote from term.

Etiology

Although the precise etiology of PE remains uncertain, numerous factors are associated with elevated risk (Table 12.3). Up to 10% of primigravid patients have mild PE, and approximately 1% have severe disease. The most widely accepted theory for the pathophysiology of PE is based on pathologic observations in the placenta indicating hypoperfusion in the maternal spiral arteries with resultant hypoxia. The placenta then releases substances into the maternal circulation that adversely affect maternal endothelial function, leading to the clinical syndrome of widespread vascular dysfunction, which is recognized as the syndrome of PE (Myers and Baker, 2002). Individual responses to the process of progressive vascular dysfunction vary in severity and timing in a manner that seems to have genetic, familial, and immunologic components. For example, PE occurring in a first-degree relative confers a fourfold increase in risk of the disease in siblings and children (Chesley and Cooper, 1986). Population studies have suggested that women exposed to the antigenic effects of sperm before conception have a lower rate of PE than do women who conceive with lesser degrees of exposure, although the evidence is inconclusive (Koelman et al., 2000).

The endothelial dysfunction that characterizes PE (Roberts, 1999) manifests as greater reactivity to circulating vasoconstrictors such as angiotensin, reduced production of endogenous vasodilators such as prostacyclin and nitric oxide (Ashworth et al., 1997), increased vascular permeability, and an increased tendency toward platelet consumption and coagulopathy. The end result is

• BOX 12.2 Management of Pregnant Women With Gestational Hypertension or Preeclampsia

Women With Gestational Hypertension or Preeclampsia Without Severe Features

Monitoring

- Fetal movement daily
- BP checks twice weekly
- Platelet counts and liver enzymes weekly
- Fetal growth sonography every 2–4 weeks
- If fetal growth restriction is detected, assess umbilical artery Doppler.

Avoid

- Antihypertensive medications unless >160/110 mmHg
- Strict bed rest prescription

Delivery

- At or beyond 37 0/7 weeks unless PE with severe features
- Magnesium sulfate need not be administered for the prevention of eclampsia.
- Regional neuraxial anesthesia (spinal or epidural) may be performed.
- Monitoring of BP should be performed for the first 72 h and again at 7–10 days.

Women With PE and Severe Features

- Administer parenteral magnesium sulfate and continue without interruption until at least 24–48 h postpartum.
- If 34 0/7 weeks or more, deliver after maternal stabilization
- If less than 34 0/7 weeks
 - Delivery may be delayed in facilities with adequate maternal and neonatal intensive care while antenatal corticosteroids for fetal lung maturity are administered.
 - Delivery should not be delayed if there is coexisting uncontrollable hypertension, eclampsia, pulmonary edema, abruption placentae, or nonreassuring fetal status.
- If previable gestational age, deliver soon after maternal stabilization
- If sustained systolic BP >160 mmHg and/or diastolic BP >110 mmHg, administer antihypertensive medication.

Prevention of Recurrent Preeclampsia

If prior PE and delivery occurred prior to 34 0/7 weeks, begin daily low-dose aspirin (81 mg) prior to 15 weeks.

BP, Blood pressure; PE, preeclampsia.

Data from American College of Obstetricians and Gynecologists. Hypertension in Pregnancy. Washington, DC: American College of Obstetricians and Gynecologists; 2013.

TABLE 12.3 Risk Factors for Development of Preeclampsia

| Factor | Relative Risk |
|-------------------------------------|---------------|
| Primigravida | 3 |
| Age >40 years | 3 |
| African-American race | 1.5 |
| Family history | 5 |
| Chronic hypertension | 10 |
| Chronic renal disease | 20 |
| Antiphospholipid syndrome | 10 |
| Insulin-dependent diabetes mellitus | 2 |
| Multiple gestation | 4 |

hypertension, proteinuria secondary to glomerular injury, edema, and a tendency toward extravascular fluid overload with intravascular hemoconcentration.

Prediction

Perhaps one of the most important contributions that prenatal care makes to maternal and fetal outcomes is the detection of PE and the prevention of eclampsia (Karbhari et al., 1972; Backe and Nakling, 1993). A wide variety of biochemical and physical tests have been proposed as screening tools for early detection of PE (Dekker and Sibai, 1991), but even the most widely used biochemical tests have poor predictive values. Uric acid levels are elevated in many cases of PE, but the sensitivity of the measurement is low (Lim et al., 1998). Clinicians should be aware of the limitations of routine urine testing for detection of proteinuria, with standard dipstick testing being notoriously inaccurate (Bell et al., 1999).

Doppler ultrasonographic assessment of the vascular dynamics in the uterine arteries during the second trimester has been proposed as a screening tool in populations in which obstetric ultrasonography is routine (Cnossen et al., 2008). Up to 40% of women who develop PE have abnormal waveforms, and this finding was reported to be associated with a sixfold rise in the risk of PE (Papageorgiou et al., 2002). As no randomized trials to date have demonstrated convincingly the ability of uterine artery Doppler studies to predict PE, its use is currently not recommended (ACOG, 2013).

The role of angiogenic factors in the pathophysiology of PE has become increasingly clear. Vascular endothelial growth factor (VEGF) and placental growth factor (PlGF), which bind to fms-like tyrosine kinase-1 (Flt-1) and soluble fms-like tyrosine kinase-1 (sFlt-1) receptors, have a critical role in angiogenesis and placental development. Flt-1, VEGF, and PlGF factor promote angiogenesis and placental vasculogenesis, whereas sFlt-1, VEGF, and PlGF inactivate those proteins, resulting in disordered angiogenesis and endothelial dysfunction. Levels of sFlt-1 are elevated in women with PE, and these elevated levels of sFlt-1 precede the features of clinical PE.

Zeisler et al. (2016) recently reported a multicenter, prospective study of the ratio of sFlt-1 to PlGF in women between 24 weeks' and 37 weeks' gestation who presented with a clinical suspicion of PE or the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count). An sFlt-1:PlGF ratio of 38 was the optimal cutoff in distinguishing between women in whom PE would develop and those in whom it would not develop in the next week. In a validation cohort of 550 women, a ratio of 0.38 or lower had a negative predictive value of 99.3% (95% confidence interval [CI], 97.9–99.9).

Despite the clear negative predictive value of an sFlt-1:PlGF ratio of less than 38 for PE diagnosis in the subsequent week, the clinical utility of this fact in managing pregnant women remains unclear. Thus at present, serum screening for PE risk is not recommended.

Prevention

If an accurate predictor of PE could be identified, the next logical step would be the application of a preventive or ameliorative treatment. Unfortunately, attempts to identify an effective treatment have proved equally difficult. Given the recognized association between vascular endothelial dysfunction and PE, prostaglandin inhibitors have been proposed as a candidate for prophylaxis or treatment. Numerous trials (Duley et al., 2001) have been conducted

with low-dose aspirin, based on the idea that the ability of aspirin to irreversibly inhibit production of the vasoconstrictive prostaglandin thromboxane would promote greater activity of prostacyclin, a vasodilatory prostaglandin. This ability of aspirin would help to maintain patency in the maternal placental vascular bed and limit or prevent the evolution of PE.

In a recent systematic review of 34 randomized controlled trials (Bujold et al., 2010) of women at risk for recurrent PE, low-dose aspirin started at 16 weeks or earlier was associated with a significant reduction in PE (9.3% treated vs 21.3% control) and IUGR (7% treated vs 16.3% control), whereas aspirin started after 16 weeks was not. Low-dose aspirin started at 16 weeks or earlier also was associated with a reduction in severe PE (0.7% treated vs 15.0% control) and preterm birth (3.5% treated vs 16.9% control). Of note, all studies for which aspirin had been started at 16 weeks or earlier included women identified to be at moderate or high risk for PE.

Calcium supplementation has been proposed as a preventive treatment on the basis of the known vasodilatory effect of calcium and impressive results in earlier, small studies (Atallah et al., 2000). Similarly, it has been suggested that antioxidants may have a role in PE prevention, but the only available trial to date showed mixed results, with improvements in biochemical indices in women receiving vitamins C and E, although perinatal outcomes were not different in treated and untreated groups (Chappell et al., 1999). Of concern was the finding that women in whom PE developed despite vitamin therapy had markedly worsened PE than controls in whom the disease developed.

Two Cochrane systematic reviews (Hofmeyr et al., 2010, 2014) found that daily calcium supplementation significantly reduced the risk of PE and hypertension with and without proteinuria. However, women who received calcium supplements had a significantly higher risk of developing HELLP syndrome. Calcium supplementation had no effects on the risk of developing eclampsia, maternal death, or maternal admission to the intensive care unit. There was no effect of calcium supplementation on preterm birth, although a subgroup analysis suggested that there were fewer preterm births among women who received between 1.5 g and 2 g of elemental calcium per day. There was no effect on low birth weight, admission to a neonatal intensive care unit, stillbirth, and neonatal death. Thus in populations with low calcium intake, calcium supplementation is a reasonable intervention of uncertain net benefit.

Antepartum Management

Given the current inability to predict or prevent PE in the majority of cases, clinicians should actively manage established disease and thus minimize maternal and fetal morbidity. The recognition that PE has a form with severe features is of great value in escalating management and minimizing morbidity (Box 12.3). Mild disease is generally managed expectantly with frequent fetal and maternal biophysical assessments until 37 weeks or there is evidence of severe features. The appearance of severe features mandates prompt delivery in all but highly selected cases regardless of gestational age.

Patients with a diagnosis of PE should be regularly evaluated for severe features. This includes a 24-hour urine collection; complete blood count with platelet measurements; determination of serum uric acid, blood urea nitrogen, and creatinine levels; and evaluation of liver transaminases. Fetal size should be estimated with ultrasonography; the presence of IUGR (estimated fetal weight less

• BOX 12.3 Preeclampsia and Severe Features

Preeclampsia Diagnosis

- Systolic blood pressure ≥ 140 mmHg or diastolic pressure of ≥ 90 mmHg twice at least 4 h apart
- Proteinuria ≥ 300 mg/24 h (not required for diagnosis)

Severe Features

- Systolic blood pressure ≥ 160 mmHg or diastolic pressure of 110 mmHg on two occasions at least 4 hours apart while the patient is on bed rest
- Pulmonary edema
- HELLP syndrome: thrombocytopenia (platelet count $<100,000/\mu\text{L}$), elevated liver enzymes to twice normal concentration, severe persistent right upper quadrant or epigastric pain
- Renal dysfunction with serum creatinine concentration >1.1 mg/dL or a doubling of the serum creatinine concentration in the absence of other renal disease
- Symptoms suggestive of end-organ involvement: headache, visual disturbance, epigastric, or right upper quadrant pain
- Eclampsia

From American College of Obstetricians and Gynecologists; Task Force on Hypertension in Pregnancy. Hypertension in pregnancy. Report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy. *Obstet Gynecol.* 2013;122:1122–1131.

than the 10th percentile), while no longer a criterion for severe PE, is a sign of jeopardy for the fetus. Patients with mild disease at 37 weeks' gestation or more should be delivered, because prolonging pregnancy further increases the risks of maternal and fetal morbidity. Patients at earlier gestational ages should be closely monitored with sequential clinical and laboratory evaluations. Such monitoring often begins in the hospital and may be continued in an outpatient setting with appropriate supervision. Fetal well-being should be evaluated until delivery by means of kick counts and regular nonstress tests or modified biophysical profiles. There is no evidence that antihypertensive therapy influences progression of nonsevere PE, and it may actually be dangerous by masking worsening hypertension; therefore oral antihypertensive therapy should be avoided during expectant management.

Conversely, severe hypertension requires prompt treatment with rapid-acting antihypertensive agents if stroke and placental abruption are to be avoided. Intravenous hydralazine is well established as a first-line drug for this purpose, although there is a growing experience with other agents, including intravenous labetalol and oral nifedipine (Duley and Henderson-Smart, 2000a) (Table 12.4). The aim of treatment is to lower blood pressure into the mild PE range ($<160/100$ mmHg) to reduce the risk of stroke and other maternal cardiovascular complications. Parenteral magnesium sulfate to prevent eclampsia should be administered in all cases of severe disease.

Severe features of PE can also present with atypical central nervous system abnormalities with associated headache, visual deficits, confusion, seizures, and, in the most severe cases, intracranial hemorrhage. This constellation of findings, when demonstrated on brain magnetic resonance imaging, has been termed the *posterior reversible encephalopathy syndrome* (PRES). Neuroimaging typically demonstrates cerebral edema in the parietal and occipital lobes. In addition to PE/eclampsia, PRES (Postma et al., 2014) has been associated with various nonobstetric conditions such as post transplantation or with autoimmune disease, in combination with immunosuppressive therapy or high-dose chemotherapy for various

TABLE 12.4 Drugs for Acute Treatment of Hypertension in Severe Preeclampsia

| Drug | Dosage |
|-------------|---|
| Hydralazine | 5 mg IV or IM, then 5–10 mg every 20–40 min as required, to a total of 30 mg or Constant intravenous infusion 0.5–10 mg/h |
| Labetalol | 10–20 mg IV, then 20–80 mg every 20–30 min to a maximum of 300 mg or Constant intravenous infusion 1–2 mg/min |
| Nifedipine | 10–20 mg PO, repeat in 30 min, then 10–20 mg every 2–6 h |

IM, Intramuscular; IV, intravenous; PO, per oral.

malignant conditions. Long-term sequelae of PRES after PE/eclampsia and other PRES-related conditions are poorly described.

More commonly, patients show evidence of intravascular microangiopathy leading to the hemolysis, elevated liver enzymes, and low platelets of HELLP syndrome. The full-blown clinical syndrome of HELLP carries a significant maternal risk related to coagulopathy and hepatic dysfunction, even hepatic rupture (Weinstein, 1982). Most patients with HELLP never experience catastrophic features of the syndrome because delivery is initiated before their condition deteriorates to a critical level.

Preeclampsia and Fetal Risk

While the practice of prompt delivery in cases of severe PE optimizes both maternal and newborn outcome, this practice increases the incidence of prematurity and its attendant complications. IUGR is not uncommon in severe PE, and there may be evidence of progressive deterioration in fetal well-being, with progressive placental dysfunction. Infants delivered before 34 weeks' gestation will benefit from antenatal steroid therapy – even as little as 8 hours of therapy before delivery may have benefit. Even those at gestations between 34 0/7 and 36 and 6/7 weeks of gestation will derive measurable benefit from a course of maternal corticosteroids (Gyamfi-Bannerman et al., 2016). The incidence of respiratory distress syndrome is lower in infants of mothers with PE who are delivered preterm than in those of age-matched controls without antenatal steroid exposure (Yoon et al., 1980). Nonetheless, the morbidity of such infants is greater because of hypoxemic insults received in utero. Infants born to mothers with PE may also have thrombocytopenia or neutropenia, which further complicates their newborn course (Fraser and Tudehope, 1996).

Intrapartum Management

Patients with PE and severe features should be delivered expeditiously once the maternal condition is stabilized. In most cases induction of labor can be undertaken safely, reserving cesarean section for obstetric indications such as breech presentation, placenta previa, and concerning fetal status. The only exception to prompt delivery may be a case of severe PE limited to proteinuria and intermittently severe hypertension but remote from term (<28 weeks' gestation). Such patients may be managed conservatively within a high-risk

• BOX 12.4 Magnesium Sulfate Therapy for Prevention of Eclampsia

- Bolus 4–6 g IV over 20 min
- Continuous infusion 1–2 g/h
- Follow up levels every 6–8 h to target 4–6 mEq/L
- Continue infusion 24 h after delivery or 24 h after seizure if seizure occurs despite magnesium therapy

IV, Intravenous.

center while antenatal corticosteroids are administered (Sibai et al., 1990). Patients with severe PE at less than 24 weeks' gestation should be offered termination of the pregnancy.

All women with PE and severe features should receive magnesium sulfate as seizure prophylaxis (Box 12.4). Current guidelines do not require magnesium sulfate for those with gestational hypertension/PE lacking severe findings. The safety and therapeutic superiority of magnesium sulfate over other agents (e.g., diazepam) have been validated in multiple randomized trials (Duley et al., 2003).

Intrapartum blood pressure should be maintained in the mild PE range (<160/105 mmHg) using intravenous antihypertensive agents (labetalol, hydralazine, or nifedipine). Epidural anesthesia is indicated for pain control and may aid in blood pressure management. Careful attention to fluid balance, especially avoiding overload, should be maintained. After delivery, the preeclamptic process typically begins to resolve rapidly.

Eclampsia

Eclampsia, by definition a “severe feature,” is the occurrence of generalized tonic-clonic seizures in association with PE. It affects approximately 1 in 2500 deliveries in the United States and may be much more common in developing countries, affecting as many as 1% of parturients. Up to 10% of maternal deaths are due to eclampsia in the United States (Creanga et al., 2015).

Most cases of eclampsia occur immediately prior to or within 24 hours of delivery. Almost half of seizures occur before the patient's admission to the labor and delivery department, approximately 30% are intrapartum, and the remainder are postpartum. There is a considerable drop in the risk of eclampsia by 48 hours postpartum, with seizures occurring in less than 3% of women beyond that time. Most patients have antecedent symptoms that

are suggestive of PE, although in some cases eclampsia may occur without warning. If eclampsia is left untreated, repetitive seizures become more frequent and of longer duration, and ultimately status eclampticus may develop. Maternal and fetal mortality are as high as 50% in severe cases, especially if the seizures occur while the patient is remote from medical care.

Randomized controlled trials have demonstrated the clear superiority of magnesium sulfate for the treatment of eclampsia over all other anticonvulsants (Duley and Gulmezoglu, 2002; Duley and Henderson-Smart, 2002b, 2002c). Intravenous magnesium sulfate is given as a 4 g bolus over 5 minutes followed by a maintenance infusion of 1–2 g/h for 24–48 hours after delivery. Subsequent seizures can be treated with further bolus injections. In refractory cases, second-line treatment with other anticonvulsants may be required. Rarely, the patient may require pharmacologic paralysis and mechanical ventilation.

Delivery after an eclamptic seizure should take place expeditiously but in a controlled, careful manner. There is little value in performing an emergency cesarean section (Coppage and Polzin, 2002) in response to a seizure. Stabilization and optimization of both maternal and fetal status are important prerequisites for delivery procedures. Once magnesium sulfate has been administered and maternal vital signs controlled, vaginal delivery is preferable in most cases. Potential indications for cesarean include a significantly unfavorable cervix, evidence of ongoing fetal compromise, or inability to achieve acceptable blood pressure control. Infants born to mothers after eclampsia require careful observation after birth.

Prenatal Drug Exposure

LINDA D. WALLEN AND CHRISTINE A. GLEASON

KEY POINTS

- National and global substance use have reached epidemic proportions.
- The legalization of marijuana has resulted in new concerns for fetal and infant exposure, with only a minor increase in our knowledge of the short- and long-term effects of marijuana in this population.
- The recent focus of perinatal substance use has grown to include widely prescribed substances, including opiates and antidepressants.
- The importance of establishing and maintaining consistent protocols in managing neonatal abstinence syndrome (NAS) has been clearly demonstrated.
- For women with substance use or misuse, whether licit or illicit, the choice to breastfeed is often challenging, and healthcare professionals are equally challenged in making recommendations. The known benefits of breastfeeding and human milk must be weighed against the potential risks to the infant, most of which are not well understood.

Substance use and misuse during pregnancy has been recognized as a problem for more than a century, but in the past decade the problem has reached near epidemic proportions. This has been due in part to increasingly widespread use of prescription painkillers, sedatives, and antidepressants in the United States. Prenatal exposure to psychotropic substances, both legal (such as alcohol, nicotine, prescription painkillers, and, recently, cannabinoids) and illegal (such as heroin, cocaine, and methamphetamines) can cause maternal, fetal, and neonatal complications. These include poor fetal growth, preterm birth, placental abruption, fetal distress, spontaneous abortion, stillbirth, fetal malformations, neonatal neurobehavioral dysfunction, and increased risk for sudden infant death syndrome (SIDS). Although substance abuse occurs in all socioeconomic classes, illegal drug abuse is more frequently associated with unhealthy lifestyles, poor access to prenatal care, untreated health problems, poverty, stress, and psychological disorders. Because of these socioeconomic confounders as well as the confounders of polysubstance exposure and the influence of various postnatal environmental factors, it is often difficult to determine the effects of maternal use of one specific drug on the fetus and newborn. This chapter addresses the epidemiology of perinatal substance use and abuse; the effects of specific drugs on the fetus and newborn; maternal issues and their effects on the newborn; identification of pregnancies and babies at risk; management of drug-exposed neonates; and the long-term effects of perinatal substance exposures. The discussion will focus

on substances that are known, or believed, to be associated with significant perinatal and neonatal morbidity: alcohol, tobacco, nicotine, opioids, cocaine, marijuana, and methamphetamine.

Epidemiology of Perinatal Substance Exposure

Prevalence

According to a 2014 national survey, approximately 10% of Americans aged 12 years or older used an illicit drug in the past 30 days. This prevalence rate is higher than in any year from 2002 through 2013 and has been driven primarily by increasing marijuana use and the nonmedical use of prescription pain relievers (SAMHSA, 2014; Center for Behavioral Health Statistics and Quality, 2015).

Determining prevalence rates for perinatal substance use, whether in general or for a specific substance, is quite challenging. Under-reporting of substance use by pregnant women, unreliable drug use survey and detection methods, frequent polydrug/substance use, and differing societal attitudes toward use of illicit and licit substances by pregnant women are just a few of those challenges. There are, nevertheless, several sources for data regarding perinatal substance exposure. Long-term follow-up studies of perinatal substance exposure, such as the Maternal Lifestyle Study developed in the early 1990s to follow substance-using pregnant women and their offspring, have published data regarding prevalence of specific drug exposures at the initiation of those studies (Shankaran et al., 2007). But that epidemiologic data, now decades old and with new ascertainment methodologies and social changes, have limited applicability to the present.

Another data source is the Substance Abuse and Mental Health Services Administration (SAMHSA), an agency of the US Department of Health and Human Services, which conducts an annual US National Survey on Drug Use and Health (NSDUH), periodically updating and revising their methods. Data from the 2013 survey revealed that 5.4% of pregnant women 15–44 years old reported current illicit drug use, higher than the 2005–2006 survey results (4.0%) and lower than the rate among women in this age group who were not pregnant (11.4%). The rates of illicit drug use by pregnant women also varied considerably by age group – 14.6% among pregnant women 15–17 years old, 8.6% among women 18–25 years old, and 3.2% among women 26–44 years old. Regarding alcohol, 9.4% of pregnant women 15–44 years old reported current alcohol use, lower than the 12% reported use in the 2005–2006 survey and significantly lower than the rates for

nonpregnant women (55.4%). Regarding cigarette smoking, 15.4% of pregnant women reported cigarette use, not significantly different from 2005–2006 (16.5%) but significantly lower than the rate for nonpregnant women (24.0%) (SAMHSA, 2014).

PRAMS, the Pregnancy Risk Assessment Monitoring System, provides another source for information on substance exposure before, during, and after pregnancy. Developed in 1987, PRAMS is a cooperative surveillance project of the US Centers for Disease Control and Prevention (CDC) and individual state health departments. It is designed to monitor maternal behaviors and experiences among women who deliver liveborn infants and currently includes 40 states and New York City, covering about 78% of all US births. PRAMS surveillance data results have historically demonstrated wide geographic, age-related, and racial/ethnic variation in tobacco, alcohol, and illicit drug use. For example, in a 2009 survey, an average of 54.2% of women 18–44 years old reported alcohol use during the 3 months prior to becoming pregnant. The highest rate was reported among whites (65.7%) and those 35–44 years old (56.5%). There was remarkable variation between states, ranging from 24% in Utah to 71.6% in Vermont (Centers for Disease Control and Prevention, 2014a). Pregnant women are more likely to decrease both recreational substance and “hard drug” use once they know they are pregnant. However, there is wide variation among substances studied, depending on the success of targeted public policy campaigns, licit versus illicit substances, and availability of treatment programs for substance-abusing or dependent women. For example, the 2013 NSDUH data regarding alcohol use in pregnancy showed that current alcohol use among pregnant women during the second and third trimesters was lower than during the first trimester (5.0 and 4.4% vs 19.0%). Disappointingly, there was less of a reduction in current cigarette use, with 19.9% in the first trimester, 13.4% in the second trimester, and 12.8% in the third trimester (SAMHSA, 2014).

Health Policy

In the 1980s, with rising cocaine use and the emergence of crack cocaine, national attention was turned to drug use during pregnancy, with a general public outcry being the result. Children born to crack addicts were widely believed to be irrevocably damaged, and public opinion was that mothers should be punished. As the foster care system became overwhelmed, and as evidence to the contrary emerged, public opinion regarding prenatal drug use began to shift, turning more toward maternal treatment and prevention rather than punishment. As Lester et al. (2004) stated, the initial overreaction of the public “in which drug-exposed children were characterized as irrevocably and irreversibly damaged” shifted “to a perhaps equally premature excessive ‘sigh of relief’ that drugs such as cocaine do not have lasting effects, especially if children are raised in appropriate environments.”

Unfortunately, this change in the public discourse regarding health policy interventions for substance use and abuse during pregnancy has not yet led to significant changes in the availability of women-centered drug treatment services, although the need for, and effectiveness of, such treatment is high (Terplan et al., 2015a). The focus of current policy is (or should be) to provide appropriate medical care for substance-using pregnant women, including medical management of their chemical dependency and programs to decrease substance use during pregnancy. However, there is still significant stigmatization of individuals with substance abuse disorders and pregnant women suffer additional stigma due to the potential for fetal harm, thus calling into question maternal

“fitness,” which may lead to a number of punitive measures. As Terplan et al. (2015b) recently wrote, “pregnant women who use substances deserve compassion and care, not pariah-status and punishment.” Further, there remains the important step of recognizing that “the idea that illegal drugs are more harmful to the unborn fetus than legal drugs is incorrect” (Thompson et al., 2009). Future research and intervention need to include programs to educate women of childbearing age of the significant effects of both legal and illegal substance use on the early-gestation fetus, starting even before pregnancy may be recognized.

A promising step in the right direction was recently taken by the US Congress, which turned its attention to increasingly widespread prescription opioid use/misuse and the resulting neonatal abstinence syndrome (NAS) epidemic. Lawmakers passed the “Protecting Our Infants” Act of 2015, which aims to reduce the number of newborn infants exposed to opioids and who may thus develop NAS. This act of Congress calls for the development of recommendations, programs, strategies, and research relevant to prenatal opioid use by the Agency for Healthcare Research and Quality and the Department of Health and Human Services as well as the provision of assistance to states by the CDC in collecting relevant public health data.

Perinatal Exposure to Specific Substances (Tables 13.1–13.2)

Alcohol

History/Epidemiology

Before 1970, the detrimental effects of alcohol abuse during pregnancy were believed to be related only to drunkenness, such as an increased risk for accidents. There was a widely held belief that the placenta formed a protective barrier between alcohol and the fetus. This belief was finally repudiated by studies in the United States (Jones and Smith, 1973) and France (Lemoine et al., 1967) describing fetal alcohol syndrome (FAS). These studies led to the 1989 US federal law requiring that warning labels be placed on all alcoholic beverage containers regarding alcohol-related birth defects. In 2005, the Surgeon General reissued an advisory for women who are, or might become pregnant – urging abstinence from alcohol consumption to eliminate the risk for fetal alcohol spectrum disorders. Despite this extensive public health campaign, a CDC analysis of 2011–2013 Behavioral Risk Factor Surveillance System data found that among pregnant women, the prevalence of any alcohol use was 10.2% and of binge drinking was 3.1%. This was significantly lower than the prevalence among nonpregnant women 15–44 years old (53.6% and 18.2%, respectively) but disappointingly similar to prevalence estimates reported for 2006–2010. A comprehensive approach is needed to achieve the *Healthy People 2020* objectives, which are to increase the percentage of pregnant women reporting abstinence from any alcohol use to 98% and to increase the percentage reporting abstinence from binge drinking to 100% (Centers for Disease Control and Prevention, 2015).

Pharmacology and Biologic Actions

Alcohol is a mood-altering substance that enhances the effects of the inhibitory neurotransmitter γ -aminobutyric acid and lessens the effect of the excitatory neurotransmitter glutamate, thus acting as a central nervous system (CNS) depressant or sedative. Alcoholic beverages come in many forms, and for centuries they have been

From Behnke M, Smith VC, Committee on Substance Abuse, Committee on Fetus and Newborn. Prenatal substance abuse: short- and long-term effects on the exposed fetus. *Pediatrics*. 2013;131:e1009–e1024.

consumed for diverse reasons: celebrations, relaxation, religious ceremonies, and medicinal purposes (alcohol is a sedative and tocolytic agent). The alcohol contained in alcoholic beverages is ethanol, which is absorbed in the digestive tract and into the body fat and bloodstream. Ethanol is metabolized to acetaldehyde by alcohol dehydrogenase (ADH), primarily in the liver. ADH is then metabolized to acetate by aldehyde dehydrogenase and eventually eliminated as water and CO₂. Although acetaldehyde is short-lived, it can cause significant tissue damage, which is particularly evident in the liver, where most alcohol metabolism takes place. Pregnant women have slower rates of alcohol clearance, probably related to hormonal alterations in the activity of the alcohol-metabolizing enzymes; this leads to slower clearance of alcohol compared with nonpregnant women consuming the same amount of alcohol (Shankaran et al., 2007).

Complications of Pregnancy

Heavy drinking carries a higher risk of cardiovascular and hepatic complications in women compared with men, and the alcohol-associated mortality rate is also considerably higher (Smith and Weisner, 2000). These factors alone can clearly complicate a woman's pregnancy. In addition, nutritional deficiencies and poor diet can affect general health and dentition, which can negatively affect a pregnancy. Alcoholism is a chronic disease that is often progressive and can be fatal. Pregnant alcoholics often have related medical disorders such as cirrhosis, pancreatitis, and alcohol-related neurologic problems. These disorders can affect the health and well-being of their fetus.

Alcohol affects prostaglandin levels, increasing levels of its precursors in human placental tissue and thus affecting fetal development and parturition. In fact, researchers have used this

knowledge to test the effect of aspirin, which inhibits alcohol-induced increases in prostaglandin levels, on reducing alcohol-induced fetal malformations in a mouse model (Randall, 2001). Specific obstetric complications of heavy drinking may relate to alterations in prostaglandin levels, including an increased risk for spontaneous abortion, placental abruption, and alcohol-related birth defects such as FAS.

Fetal Growth

Intrauterine growth restriction (IUGR) is one of the most consistent findings of prenatal exposure to alcohol (Hannigan and Armant, 2000). Growth deficit begins in utero and continues throughout childhood (Williams et al., 2015). The facial features and the growth restriction become less noticeable during adolescence and puberty (Streissguth et al., 1991; Williams et al., 2015).

Fetal Alcohol Spectrum Disorders

FAS was first described by Lemoine et al. (1967), a Belgian pediatrician who observed a common pattern of birth anomalies in children born to alcoholic mothers in France. This description was followed by a landmark article by Jones and Smith (1973) that reported similar features in several children born to alcoholic mothers in the United States.

It is unclear how much alcohol exposure is necessary to cause fetal teratogenicity, and even high consumption levels do not always result in the birth of a child with FAS (Abel and Hannigan, 1995). However, a woman with a previously affected child is at increased risk for having a child with FAS if she consumes alcohol during a subsequent pregnancy. The adverse effects of alcohol on the fetus are related to gestational age (GA) at exposure, the amount of alcohol consumed, and the pattern of consumption (e.g., binge drinking), maternal peak blood alcohol concentrations, maternal alcohol metabolism, and the individual susceptibility of the fetus. Studies show that maternal peak blood alcohol levels are affected by maternal nutrition, age, body size, and genetic disposition (Maier and West, 2001). In addition, various risk factors increase susceptibility to FAS, including advanced maternal age and confounding factors such as nonwhite race, poverty, and socioeconomic status (Abel, 1995; May and Gossage, 2001). In the United States, the incidence of FAS is tenfold higher for African Americans living in poverty than for white middle-class women (Abel, 1995). Despite the differences in incidence of FAS worldwide, reports consistently indicate poverty or socioeconomic status as major determinants of FAS (Abel, 1995; May et al., 2000).

Features of FAS include characteristic facial dysmorphism (short palpebral fissures, midface hypoplasia, broad flat nasal bridge, flat philtrum, and thin upper lip [Fig. 13.1]), prenatal and postnatal growth deficiency, and variable CNS abnormalities. Skeletal anomalies, abnormal hand creases, and ophthalmologic, renal, and cardiac anomalies have been described in children with FAS but less frequently than the facial dysmorphism and CNS abnormalities that include structural brain defects (e.g., dysgenesis of the corpus callosum and cerebellar hypoplasia), cognitive abnormalities, delayed brain development, and signs of neurologic impairment, including lifelong behavioral and psychosocial dysfunction. In 1996, the Institute of Medicine further defined the criteria for the diagnosis of FAS and proposed a new term – alcohol-related neurodevelopmental disorder (ARND). This term includes structural CNS and cognitive abnormalities in children with confirmed fetal exposure to alcohol. Unlike FAS, a diagnosis of ARND does not require the presence of facial or other physical abnormalities. In 2000, the American Academy of Pediatrics (AAP) Committee on

FACIES IN FETAL ALCOHOL SYNDROME

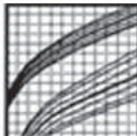

• **Fig. 13.1** Facies in Fetal Alcohol Syndrome. (From Streissguth AP, Little RE. Alcohol, pregnancy, and the fetal alcohol syndrome, ed. 2, unit 5 of *Alcohol use and its medical consequences: a comprehensive slide teaching program for biomedical education*. Developed by Project Cash of the Dartmouth Medical School. Reproduced with permission from Milner-Fenwick, Inc., Timonium, Michigan, 1994.)

Substance Abuse published these new definitions with an explanatory drawing (Fig. 13.2), and their recommendations were updated in 2015 (Williams et al., 2015).

The incidence of FAS in the United States has been estimated to vary from 0.5–9 cases per 1000 live births (Bertrand et al., 2005; Williams et al., 2015). FAS is recognized more frequently in the United States than in other countries and is most common (4.3%) among women who report heavy drinking (Abel, 1995). Accurate incidence and prevalence rates of FAS are difficult to obtain because of wide variations in methodologies used for estimation of rates and because the clinical diagnosis is often missed in the neonatal period.

FAS is diagnosed from the history and physical findings. No laboratory tests are available for clinical use to quantify the extent of alcohol exposure during fetal life. There are also no clinical methods for validating maternal self-reporting of alcohol use, quantifying the level of fetal exposure, or predicting future disability after fetal exposure. Koren et al. (2002) have proposed meconium fatty acid ethyl ester levels as a potential biologic marker for fetal alcohol exposure, but relevance of these levels to childhood outcomes remains to be studied. Investigators have shown that pediatricians fail to recognize FAS in the newborn and do not always inquire about alcohol exposure during pregnancy (Stoler and Holmes, 1999). One promising screening tool is the use of averaged cranial ultrasound images to examine the size and shape of the corpus callosum, which is typically dysgenic in FAS (Bookstein et al., 2005). Guidelines to aid in the earlier recognition and referral of infants and children with FAS and fetal alcohol spectrum disorder have been published recently (Bertrand et al., 2005; Hoyme et al., 2005). FAS is not a problem just for neonatologists. Adolescents who were exposed prenatally to alcohol have a different approach to alcohol than their nonexposed peers, with an increased risk for earlier use and subsequent alcohol abuse (Baer et al., 2003). In an Australian study of education records at age 8–9 years old, children with heavy prenatal alcohol exposure during the first trimester or binge drinking later in pregnancy were twice as likely not to achieve the benchmark for reading and writing (O’Leary et al., 2013b). Children with FAS continue to have serious disabilities into adulthood (Williams et al., 2015). Although the facial features and

Adapted from *Fetal Alcohol Syndrome: Diagnosis, Epidemiology, Prevention, and Treatment*. 1996;4–5. Letter designations in the figure indicate the following:

- A. Confirmed maternal alcohol exposure indicates a pattern of excessive intake characterized by substantial, regular intake or heavy episodic drinking. Evidence of this pattern may include frequent episodes of intoxication, development of tolerance or withdrawal, social problems related to drinking, legal problems related to drinking, engaging in physically hazardous behavior while drinking, or alcohol-related medical problems such as hepatic disease.
- B. Evidence of a characteristic pattern of facial anomalies that includes features such as short palpebral fissures and abnormalities in the premaxillary zone (e.g., flat upper lip, flattened philtrum, and flat midface)
- C. Evidence of growth retardation, including at least one of the following:
- Low birth weight for gestational age
 - Decelerating weight over time not caused by nutrition
 - Disproportional low weight to height
- D. Evidence of CNS neurodevelopmental abnormalities, including at least one of the following:
- Decreased cranial size at birth
 - Structural brain abnormalities (e.g., microcephaly, partial or complete agenesis of the corpus callosum, cerebellar hypoplasia)
 - Neurologic hard or soft signs (as age appropriate), such as impaired fine motor skills, neurosensory hearing loss, poor tandem gait, poor eye-hand coordination
- E. Evidence of a complex pattern of behavior or cognitive abnormalities that are inconsistent with developmental level and cannot be explained by familial background or environment alone, such as learning difficulties; deficits in school performance; poor impulse control; problems in social perception; deficits in higher level receptive and expressive language; poor capacity for abstraction or metacognition; specific deficits in mathematical skills; or problems in memory, attention, or judgment

F. Birth defects associated with alcohol exposure include:

| | | |
|----------|--|---|
| Cardiac | Atrial septal defects Ventricular septal defects | Aberrant great vessels Tetralogy of Fallot |
| Skeletal | Hypoplastic nails Shortened fifth digits Radioulnar synostosis Flexion contractures Camptodactyly | Clinodactyly Pectus excavatum and carinatum Klippel-Feil syndrome Hemivertebrae Scoliosis |
| Renal | Aplastic, dysplastic, hypoplastic kidneys Horseshoe kidneys | Ureteral duplications Hydronephrosis |
| Ocular | Strabismus Retinal vascular anomalies | Refractive problems Secondary to small globes |
| Auditory | Conductive hearing loss | Neurosensory hearing loss |
| Other | Virtually every malformation has been described in some patient with FAS. The etiologic specificity of most of these anomalies to alcohol teratogenesis remains uncertain. | |

Alcohol-related effects indicate clinical conditions in which there is a history of maternal alcohol exposure and where clinical or animal research has linked maternal alcohol ingestion to an observed outcome. There are two categories, alcohol-related neurodevelopmental disorder and alcohol-related birth defects, which may cooccur. If both diagnoses are present, then both diagnoses should be rendered.

• **Fig. 13.2** Diagnostic Classification of Fetal Alcohol Syndrome and Alcohol-Related Effects. CNS, Central nervous system; FAS, fetal alcohol syndrome. (From the American Academy of Pediatrics. Committee on Substance Abuse and Committee on Children with Disabilities. Fetal alcohol syndrome and alcohol-related neurodevelopmental disorders. *Pediatrics*. 2000;106:358–361. Reproduced with permission from the American Academy of Pediatrics, 2000.)

growth restriction are no longer as distinctive as during childhood, mental retardation continues to have a significant effect. Adults with FAS have behavior, socialization, and communication dysfunction, and on average they function at the second-grade or third-grade level. A significant number of FAS patients do not achieve fully independent living. Earlier recognition and intervention for children with FAS and its variants may help to minimize eventual adulthood disabilities and help to prepare adolescents and young adults with the disorder for independent living (Bertrand et al., 2005; Williams et al., 2015).

Cigarette Smoking and Nicotine

History/Epidemiology

Nicotine – in the form of cigarettes (including electronic cigarettes), smokeless tobacco, and nicotine replacement patches – remains the substance used most often during pregnancy and the most influential factor adversely affecting perinatal outcomes, particularly preterm birth. Cigarette smoking in the United States has decreased significantly over the past 25 years, thanks to a number of effective public health strategies, including funding tobacco control programs, increasing the price of tobacco products, enacting comprehensive smoke-free policies, and reducing tobacco advertising and promotion. Unfortunately, these efforts have not been as effective for pregnant women. Data from the 2012–2013 NSDUH survey revealed that 24% of reproductive-aged women and 15% of pregnant women smoked cigarettes (SAMHSA, 2014). This is a reduction in prevalence compared to 2002–2003 (30% and 18%, respectively) but far lower than was hoped and considerably lower than the targets set by the *Healthy People 2020* initiative to increase abstinence from cigarette smoking to 98.6% of pregnant women.

Women who smoke during pregnancy are more likely to use opioids, alcohol, cocaine, amphetamines, and marijuana than women who do not smoke (SAMHSA, 2014). Cigarette smoking is especially prevalent among pregnant women with opioid use disorders, with smoking estimates as high as 95% (Ram et al., 2015). Treatment programs for substance use disorders, particularly those targeted at opioid use, are in an ideal position to develop concomitant smoking cessation programs.

Pharmacology and Biologic Actions

Cigarette smoke contains a complex mixture of approximately 4000 compounds, including nicotine and carbon monoxide, which can adversely affect the fetus (Lester et al., 2004). In rodents, nicotine releases chemicals in the reward center of the brain, which likely triggers the euphoria that smokers experience. Nicotine activates nicotinic acetylcholine receptors, and these receptors remain depressed for a longer time after their activation stops, which probably accounts for compulsive smoking (Morrell et al., 2008). Nicotine crosses the placenta and concentrates in fetal blood and amniotic fluid, where its levels significantly exceed maternal blood concentrations (Haustein, 1999). The serum concentration of cotinine, the primary metabolite of nicotine, is used to quantitate the level of smoking and fetal exposure. Cotinine has a half-life of 15–20 hours, and because its serum levels are tenfold higher than those of nicotine, this substance may represent a better marker for intrauterine exposure (Lambers and Clark, 1996).

Complications of Pregnancy

Although the exact mechanism of the adverse effects of smoking on pregnancy is unknown, cigarettes contain numerous potentially

toxic compounds that affect fetal health in a number of ways. Nicotine and its metabolites can act as vasoconstrictors, and a study in pregnant rhesus monkeys demonstrated a nicotine-associated decrease in uterine blood flow (Jauniaux and Burton, 2007; Salihu and Wilson, 2007), which might provide a partial explanation for the association between maternal cigarette smoking and low birth weight. Theories regarding mechanisms for the adverse effects of smoking on fetal health include direct vasoconstrictive effects of nicotine on uteroplacental blood flow, the induction of fetal hypoxia from carbon monoxide production, direct toxic effects and indirect effects of altered maternal nutritional intake, and altered maternal and placental metabolism (Jauniaux and Burton, 2007). When pregnant women smoke cigarettes, the resulting increased levels of carbon monoxide cross the placenta and form carboxyhemoglobin in the fetus, with resulting hypoxemia (Jauniaux and Burton, 2007). Supporting this theory, serum erythropoietin levels are higher in tobacco smoke-exposed infants at delivery, a finding that is presumed to reflect fetal hypoxia (Jazayeri et al., 1998). In addition to the fetal hypoxia theory, there have recently been studies demonstrating that nicotine may act as a developmental neurotoxin targeting nicotinic acetylcholine receptors (Lester et al., 2004; Jauniaux and Burton, 2007) and may disturb protein metabolism during gestation, leading to decreased serum amino acids in umbilical cord blood (Jauniaux et al., 2001).

Maternal smoking has also been shown to affect the length of gestation in a dose-dependent manner, with a higher risk of preterm delivery (Jaakkola et al., 2001) and a twofold increase in the incidence of placental abruption (Jauniaux and Burton, 2007). Perinatal mortality is increased in pregnant smokers, probably reflecting the increases in rates of prematurity, placental abruption, and placenta previa in women who smoke. Mothers who smoke during pregnancy commonly continue to smoke during their infants' childhood. Asthma and other chronic conditions are more common in infants who are exposed to passive smoking (Burke et al., 2012).

Fetal Growth

The effect of smoking on fetal growth is significant and dose dependent (Jauniaux and Burton, 2007). Studies have shown lower birthweights associated with levels of nicotine exposure, with a 1 g reduction in birthweight observed for every microgram per milliliter increase in maternal serum cotinine level (Eskenazi et al., 1995). Investigators have shown a dose-dependent relationship between the amount of smoking and the extent of fetal growth restriction and birthweight reduction (Jaakkola et al., 2001; Jauniaux and Burton, 2007).

Both reducing and ceasing cigarette smoking during pregnancy have been shown to be beneficial and to lead to improved fetal growth. Lieberman et al. (1994) have shown that if pregnant women stop smoking during the third trimester, their infants' weights are indistinguishable from those of a nonsmoking population. Other investigators report that even a modest reduction in smoking is associated with improved fetal growth (Walsh et al., 2001).

Marijuana

History/Epidemiology

Marijuana, or cannabis, has been used for medicinal purposes for over 5000 years, but it was not classified as a legitimate medical compound in the *United States Pharmacopeia* until 1851. In 1937, marijuana was criminalized in the United States (against the advice of the American Medical Association) and was given schedule I status, although patients could still obtain it at cannabis dispensaries

and a growing number of statewide programs. Several cannabis-derived medicines have been developed and are available in the United States and Canada, including dronabinol (schedule III) and nabilone (schedule II), both of which were US Food and Drug Administration approved in 1985 for treatment of nausea and vomiting associated with cancer chemotherapy (Borgelt et al., 2013). Recreational use of marijuana increased in the 1960s, especially among young people, and today it is the most commonly used illicit drug in the United States (SAMHSA, 2014; Center for Behavioral Health Statistics and Quality, 2015).

In the United States, a major shift in societal attitudes toward marijuana has occurred in the past decade, leading to increasing legalization of its use as well as increased availability and potency. This societal shift has largely been due to the widespread belief that marijuana is less “risky” compared to most other substances (both licit and illicit) as well as to growing belief in, and some evidence for, its potential medicinal properties. Although marijuana use remains illegal (in 2016) under federal law (Title 21 US State Code Controlled Substances Act), more than half of US states and the District of Columbia have legalized “medical” marijuana use, and several have also legalized recreational use for those 21 years of age and older. In 2013, 7.5% of the US population reported use of marijuana within the last month, up from 5.8% in 2007 (NIDA Nationwide Trends, 2016).

Cannabis use by pregnant women is similarly on the rise. Using US data from the 2007–2012 NSDUH, Ko et al. (2015) reported that 10.9% of pregnant women and 14% of nonpregnant women of childbearing age used marijuana in the past year and that 3.9% of pregnant and 7.6% of nonpregnant women used it in the past month. Among past-year marijuana users, near daily use was reported by 16.2% of pregnant women, and 18.1% met criteria for abuse and/or dependence. A 2010 study in the UK found that a majority of women who used cannabis prior to pregnancy continued both their use and their levels of usage while pregnant (Moore et al., 2010). An emerging concern is the use of marijuana to treat hyperemesis gravidarum or the more common “morning sickness,” with conflicting reports on its effectiveness (Westfall et al., 2006; Roberson et al., 2014).

Pharmacology and Biologic Actions

Marijuana refers to the dried leaves, flowers, stems, and seeds from the hemp plant *Cannabis sativa*, while hashish refers to the resin that the plant produces. The main psychoactive ingredient is δ -9-tetrahydrocannabinol (THC), a small, highly lipophilic molecule that binds to the endogenous cannabinoid receptors (CB1 and CB2) and modifies the release of several neurotransmitters. Its primary biologic effects include pleasant euphoria and a sense of relaxation; heightened sensory perception; increased appetite; laughter; altered perception of time; and impaired coordination, decision making, short-term memory, concentration, and learning. Less common effects include anxiety, fear, distrust, panic, and acute psychosis. Marijuana can be smoked in hand-rolled cigarettes (joints), pipes (bongs), or blunts (emptied cigars refilled with marijuana). To avoid inhaling smoke, vaporizers can be used to pull the active ingredients from the marijuana (vaping). Users can also mix marijuana in edibles such as brownies, cookies, or candy. Smoking THC-rich resins extracted from the marijuana plant, a practice called “dabbing,” is on the rise. These extracts can deliver very large amounts of THC to users.

Although controversial, there is emerging evidence that chronic marijuana users can develop dependence or addiction, as well as signs of withdrawal following abrupt discontinuation (Hasin et al.,

2015). Whether or not neonates who have had chronic perinatal marijuana exposure can experience withdrawal is unknown. THC can be stored in body tissues for as long as 30 days in chronic users. THC readily crosses the placenta and collects in the amniotic fluid, while its major metabolite does not. In an animal model, fetal plasma levels were approximately 10% of maternal levels after an acute exposure and higher after repetitive exposures (Bailey et al., 1987).

Complications of Pregnancy

There is limited evidence to suggest that marijuana use during pregnancy has significant perinatal effects. There is scant data regarding its potential effects on stillbirth, primarily because prior studies of marijuana use in pregnancy excluded women with stillbirth. Varner et al. (2014) recently reported an increased risk of stillbirth among women who used marijuana during pregnancy, as demonstrated by THC in umbilical cord homogenates, but there was partial confounding by maternal tobacco use. Studies regarding marijuana and preterm birth have yielded mixed results. Some studies suggest increased risk, while others demonstrate no association. This is probably due to poor quantification of marijuana exposure as well as lack of documentation of the indication(s) for preterm birth in many of these studies.

Regarding birth defects, the evidence is relatively clear: both prospective and retrospective studies have not demonstrated an association between marijuana use and major congenital anomalies. Unfortunately, most of these studies are based on birth defects registries with incomplete ascertainment of confounding factors and the potential for recall bias (Metz and Stickrath, 2015).

Fetal Growth

There have been numerous long-term outcome studies regarding the effect of marijuana use during pregnancy on fetal growth, and most have shown marginal to no effect (Metz and Stickrath, 2015). The Generation R Study, for example, used serial ultrasound (not birthweight) to assess fetal growth. Early gestation–exposed fetuses grew 11 g per week less than nonexposed fetuses; the effect was more pronounced if there was continued use throughout pregnancy. The clinical significance of this finding is questionable (El Marroun et al., 2009). More recently, Warshak et al. (2015) examined associations between marijuana exposure and adverse outcome, excluding women with polysubstance abuse and stratifying for concurrent tobacco use. They reported no increased risk of adverse obstetric outcomes or fetal anomalies but did note an increase in small for gestational age (SGA) infants and neonatal intensive care unit (NICU) admission.

Long-Term Effects of Perinatal Cannabis Exposure

The potential for marijuana use during pregnancy to cause adverse fetal effects is clear. Endocannabinoid receptors are found in the human fetal brain by the 14th week of gestation and while the role of these receptors is not well understood, they modulate neural proliferation, migration, and differentiation of lineage-committed cells. Both supraphysiological stimulation of the endogenous cannabinoid system and disruption of developing neurotransmitter systems by exogenous cannabinoids have the potential to adversely affect fetal brain development (Alpar et al., 2016).

Animal studies of maternal marijuana exposure have shown alterations in neurotransmitter and neuroendocrine systems of the offspring, especially the dopaminergic pathways (Fernandez-Ruiz et al., 1999) and marked increase in hyperactivity, and persistent effects on learning and memory (Antonelli et al., 2005; Moreno

et al., 2005). Jutras-Aswad et al. (2009) studied postmortem human fetal brains from 17–22 week elective terminations with a self-reported history of marijuana use during pregnancy. Reduced dopamine receptors in the amygdala were noted, with the effect most prominent in male fetuses. The finding correlated with the amount of marijuana used during pregnancy.

There have been several longitudinal studies of the effects of perinatal marijuana use and infant outcomes, including the Ottawa Prenatal Prospective Study, the Generation R Study, and the Maternal Health Practices and Child Development (MHPCD) study. These studies are flawed by several factors, including polysubstance use, variability in dosing and frequency, and reliance on self-reported use. In addition, there are the universal confounders for perinatal drug use studies such as, socioeconomic, genetic, or environmental factors. However, although the data are not strong and the effects are uncertain, these studies suggest that prenatal marijuana exposure may cause problems with neurodevelopment. The MHPCD study began subject recruitment in 1982 and continues to follow the large cohort of the offspring of pregnant women who used THC during the first trimester. At age 3 years, altered sleep patterns but no cognitive effects were reported; at age 6 years, decreased verbal reasoning if there was greater exposure; at age 10 years, decreased attention, more impulsivity, and worse academic performance in reading and spelling; and at age 14 years, lower scores in reading, math, and spelling and earlier onset of substance use. Most recently, it was reported that prenatal marijuana exposure was a significant predictor of offspring marijuana use at age 22 years (Sonon et al., 2015).

Prenatal marijuana exposure is reported to be associated with deficiencies in executive function in 9–12 year olds (Fried et al., 1998; Fried and Smith, 2001), and recent reports have found that prenatal marijuana exposure has a significant effect on school-age intellectual performance (Richardson et al., 2002; Goldschmidt et al., 2004, 2008).

Although current evidence suggests that the adverse effects of prenatal marijuana exposure are uncertain (Jaques et al., 2014; ACOG [American College of Obstetricians and Gynecologists], 2015b), this evidence is based upon studies that were often begun decades ago and thus may not be relevant to today's pregnant users. Today's marijuana is 6–7 times more potent than it was in the 1970s, and there are many more ways to consume cannabis now, some of which result in significantly higher levels, and longer duration, of the active ingredient. As Warner et al. (2014) so eloquently titled a 2014 review, "It's not your mother's marijuana."

Opioids (Including Prescription Painkillers)

History/Epidemiology

Opioid is a generic term applied to alkaloids derived from the opium poppy, to their synthetic analogues, and to compounds synthesized in the body. Opium derivatives have been used as analgesics for centuries and remain the most effective analgesics available. Opioids of clinical interest are morphine, heroin, methadone, meperidine, oxycodone, codeine, and fentanyl (Rudd et al., 2015). Perinatal problems associated with maternal opium use were first reported in the late 1800s. Since the 1950s, heroin use, particularly among women, has been endemic in most major US cities although heroin addiction during pregnancy was still relatively rare (Shankaran et al., 2007).

However, in recent years, there has been a significant increase in prescription opioid use and misuse in the United States, and this has resulted in an increase in opioid dependence and addiction.

According to the United Nations Office on Drugs and Crime, an emerging phenomenon among opioid-dependent drug users in the United States has been the replacement of synthetic opioids by heroin, due to both increased heroin availability and its lower cost. In addition, the reformulation of one of the main prescription opioids of abuse, OxyContin, now makes it more difficult to snort or inject (UN Office on Drugs and Crime, World Drug Report 2014).

Women of reproductive age have not been spared from this surge in opioid use and misuse. In a recent CDC report using commercial insurance claims and Medicaid data from 2008–2012, approximately 28% of privately insured and 39% of Medicaid-enrolled women 15–44 years old filled an opioid medication each year for five consecutive years. The most frequently prescribed opioids were hydrocodone, codeine, and oxycodone. There were significant regional and racial/ethnic differences; among privately insured women, opiate prescriptions were highest among those residing in the South and among Medicaid-enrolled women, prescriptions were highest among non-Hispanic whites. Women 15–19 years old, regardless of their healthcare coverage, were least likely to fill a prescription for an opioid (Ailes et al., 2015). Opioid prescriptions for pregnant women have similarly been increasing. Patrick et al. (2015) used prescription data for enrollees in the Tennessee Medicaid program between 2009 and 2011 and found that 28% of pregnant women filled at least one opioid prescription. Women who were prescribed opioids were more likely to have depression or anxiety disorder and to smoke tobacco, increasing the risk of their offspring developing NAS (Patrick et al., 2015). Bateman et al. (2014) studied opioid utilization in pregnancy in a large cohort of private insurance beneficiaries from across the United States from 2005–2011 and reported that opioids were dispensed to 14% of pregnant women, with approximately 6% receiving opioids during all three trimesters. The prevalence of exposure varied significantly by region, being lowest in the Northeast and highest in the South.

Pharmacology and Biologic Actions

Opioids are either drugs derived from the opium poppy or synthesized compounds that have similar biologic actions. The prototype opioid is morphine, and all opioids relate to it. For example, heroin (diacetylmorphine) exerts its effects by being metabolized to morphine, as does codeine, which is methylated morphine. Other opioids, such as methadone and oxycodone, are structurally unlike morphine but share its pharmacologic properties, because they stimulate similar opioid receptors. Specific opioid receptors (μ , δ , κ) have been identified in the nervous system and bowel that are activated by endogenous opioids, such as the naturally occurring endorphins and enkephalins (Vaccaro and Kastin, 2000). As modulators of the sympathoadrenal system, endogenous opioids are important during periods of diverse forms of stress. Activation of these receptors by the endogenous opioids has physiologic effects, including analgesia, drowsiness, respiratory depression, decreased gastrointestinal motility, nausea, vomiting, and alterations in the endocrine and autonomic nervous systems. Activation of these same endogenous opioid receptors by exogenous opioid drugs has similar clinical effects, producing euphoria, sleepiness, and decreased sensitivity to pain, as well as adverse effects such as constipation and nephrotic syndrome (ACOG, 2012).

The use of opioid drugs can result in the development of tolerance, physiologic dependence, and addiction. Tolerance leads to a shortened duration of the action of opioids and a decrease in the intensity of the drug's action, followed by the need for higher

doses to obtain the same clinical effect. Tolerance is believed to result from continued occupancy of the opioid receptor. Continuous administration of opioids therefore leads to the more rapid onset of tolerance (Suresh and Anand, 2001). With physiologic dependence, there is a need for further drug administration to prevent withdrawal symptoms (agitation, dysphoria, temperature instability). Addiction is a more severe form of dependence that involves a complex pattern of drug-seeking behavior (Christensen, 2008).

Complications of Pregnancy

Obstetric complications associated with maternal use of opioids include a higher incidence of spontaneous abortion, premature delivery, preterm labor, placental abruption, chorioamnionitis, impaired fetal growth, and fetal distress. In women who use opioids during pregnancy, the incidence of preterm labor and premature delivery ranges from 25%–35% (Fajemirokun-Odudeyi et al., 2006; Pinto et al., 2010). Maternal opioid use is also associated with higher rates of meconium-stained amniotic fluid, lower Apgar scores, and an increased incidence of syphilis, hepatitis C (HCV), and HIV infection at birth (Fajemirokun-Odudeyi et al., 2006). The rates of maternal complications of pregnancy are further increased when drug use is added to infection with HIV.

The etiology of these opioid-associated pregnancy complications is multifactorial. Maternal lifestyle, malnutrition, infections, and polydrug effects are likely to result in poor perinatal outcomes, including poor intrauterine growth and prematurity. Because the drug supply is often episodic, the pregnant addict is subject to episodes of withdrawal and overdose, thereby subjecting the fetus to intermittent episodes of hypoxia in utero, hindering growth and raising the risk of spontaneous abortion, stillbirth, fetal distress, and prematurity. Infants born to mothers who are addicted to opioids are more likely to be of low birth weight, to be premature, and to suffer from infection and perinatal asphyxia (Christensen, 2008; ACOG, 2012).

Fetal Growth

Initial reports from studies addressing the effects of maternal opioid use on the fetus suggested that infants exposed to opioids in utero have a higher incidence of IUGR and smaller head circumference (Fajemirokun-Odudeyi et al., 2006; Pinto et al., 2010). Pinto et al. (2010) reported an association with heroin abuse and methadone use and increased prematurity, low birth weight, and reduced fetal growth. However, other studies which controlled for confounding factors have not demonstrated a significant relationship between opioid use and prematurity, low birth weight, or IUGR (Sharpe and Kuschel, 2004; Minozzi et al., 2008).

Long-Term Effects of Perinatal Opioid Exposure

A number of studies suggest that exposure to exogenous opioids during fetal development may produce lifelong alterations in brain development. Significant developmental and learning deficits have been described in both methadone-exposed and heroin-exposed children. For example, Bunikowski et al. (1998) have reported a higher incidence of abnormalities in intellectual performance, developmental retardation, and neurologic abnormalities in a group of opioid-exposed infants compared with a control group. However, the exposed infants had a higher incidence of prematurity (38%) than the control infants (0) and had an unusually high incidence of seizures (15%). These important considerations temper the findings of that study.

A more recent report following a cohort of opioid-exposed infants documented lower Bayley Mental Development Index scores

at 18 months old, lower Stanford Binet Intelligence Scale scores at 3 years, and decreased scores on the Vineland Social Maturity Scale and Reynell Language Scale at 3 years (Hunt et al., 2008). However, a similar study showed no mental, motor, or behavioral deficits at 3 years after controlling for birthweight and environmental risk factors (Messinger et al., 2004). Other investigators have shown normal development for opioid-exposed infants during the first 2 years of life after data were controlled for socioeconomic status and birthweight (Behnke et al., 2013). Using regression analysis, researchers have shown that the amount of prenatal care obtained by the mother and the postnatal home environment were more predictive of the infant's future intellectual performance. Conversely, the amount of maternal opioid use during pregnancy was not found to be predictive. Ornoy et al. (2001) have shown that children exposed to heroin but adopted at an early age performed better on intelligence testing than did opioid-exposed infants who were raised in the homes of their biologic parents. The same investigators found a higher rate of attention deficit disorders in children exposed to opioids regardless of home environment, with the highest incidence in children who were raised in the homes of their biologic parents. Numerous studies point also to the importance of the home environment in optimizing child development. Variable outcomes of these studies may depend on the amount and type of drug use or on other covariates such as nutritional status, poverty, psychosocial problems, and parental educational level.

Cocaine

History/Epidemiology

The euphoria-producing effect of cocaine was exploited extensively in the United States in the late 19th and early 20th centuries, when the agent was an active ingredient in a number of widely used over-the-counter elixirs and tonics. Cocaine use markedly decreased after the Harrison Narcotic Act of 1914 and the supervening Comprehensive Drug Abuse Prevention and Control Act of 1970, which classified cocaine as a schedule II drug (i.e., one of "high abuse potential with restricted medical use," similar to opioids, barbiturates, and amphetamines). Cocaine's reputation as a glamour drug, the widely held misconception that cocaine is not addictive, and the development and marketing of "crack," a cheap version of cocaine, were major factors in the resurgence in the use of the drug. Growing concern regarding the effects of maternal cocaine use on pregnancy outcomes was one of the reasons that the US Congress passed the 1986 Narcotics Penalties and Enforcement Act, which imposed severe penalties on any person convicted of either possessing or distributing the drug; however, this law did not appreciably alter the fact that cocaine and other stimulants had become the drugs of choice for women in the United States. By the 1990s, studies based on urine toxicology screening reported a prevalence of cocaine use among pregnant women of 5% in New York City, 1.1% in a geographic sample in California, and less than 0.5% in private hospitals in Denver, Colorado (Burke and Roth, 1993). Cocaine use has been declining in North America since 2006, according to the 2014 United Nations World Drug Report, partly due to a sustained shortage, although a slight increase in prevalence has been observed in the United States, along with an increase in maritime cocaine seizures (United Nations World Drug Report, 2014).

Pharmacology and Biologic Actions

Cocaine is a highly psychoactive stimulant with a long history of abuse. A naturally occurring anesthetic of the tropane family of

alkaloids, cocaine is obtained from the *Erythroxylon coca* plant, which is indigenous to the mountain slopes of Central and South America. The coca leaf has been chewed or made into a stimulant tea by the natives of these areas to decrease fatigue and hunger. The pharmacologic actions of cocaine include inhibition of postsynaptic reuptake of norepinephrine, dopamine, and serotonin neurotransmitters by sympathetic nerve terminals, thus allowing higher concentrations of these neurotransmitters. In adults, cocaine binds strongly to neuronal dopamine reuptake transporters, thereby increasing postsynaptic dopamine at the mesolimbic and mesocortical levels and producing the addictive cycle of euphoria and dysphoria (Malanga and Kosofsky, 1999). Tryptophan uptake is similarly inhibited, altering serotonin pathways with resultant effects on sleep.

Cocaine use leads to a sense of well-being, increased energy, increased sexual achievement, and an intense euphoria or “high.” The sympathomimetic action can have potentially devastating physiologic effects on the cardiovascular system. In adults, cocaine has been associated with cerebral hemorrhage, cardiac arrest, cardiac arrhythmias, myocardial infarction, intestinal ischemia, and seizures. Chronic use is associated with anorexia, nutritional problems, and paranoid psychosis and can ultimately result in neurotransmitter depletion and a “crash,” characterized by lethargy, depression, anxiety, severe insomnia, hyperphagia, and cocaine craving.

Two forms of cocaine are commonly used – cocaine hydrochloride and cocaine base – which are either extracted by organic solvents or precipitated as crack through the use of ammonia and baking soda. Cocaine hydrochloride is a water-soluble white powder that is used orally, intranasally (“snorting”), or intravenously (“running”). Intravenous users are more likely to have a history of heroin abuse and often use the drug in combination with heroin (known as *speedballing*). Cocaine hydrochloride decomposes on heating and is, therefore, cocaine converted to the free base for inhalation. “Freebasing” involves extracting cocaine from aqueous solution into an organic solvent such as ether. Crack, the most widely available form of freebase, is almost pure cocaine; when smoked, it readily enters the bloodstream to produce levels similar to those occurring with intravenous use. Crack cocaine is popular in urban minority communities, where it may be smoked in combination with phencyclidine or PCP (known as *spacebasing*). Crack smoking appears to be particularly reinforcing and is associated with compulsive use, binges, and acceleration of the addictive process.

Cocaine and some of its metabolites readily cross the placenta and achieve pharmacologic levels in the fetus (Schenker et al., 1993). Amniotic fluid may serve as a reservoir for cocaine and its metabolites and prolong exposure to vasoactive compounds. The extent to which cocaine or its metabolites are responsible for aberrant fetal growth, neurodevelopmental sequelae in exposed infants, and the range of congenital malformations reported in the literature may be less than suggested by uncontrolled case reports early in the cocaine-epidemic era. The confounding effects of increased use of multiple drugs, tobacco, alcohol, nutritional deficits, and decreased use of prenatal care among cocaine users make interpretation of the causal relationships between gestational cocaine exposure and intrauterine growth and subsequent neurobehavioral development difficult (Pinto et al., 2010). These identified confounders might serve to explain the reported effects attributed to cocaine in clinical series, although significant effects on the fetus and newborn have been reported in more recent studies that controlled for many confounders (Bada et al., 2002; Shankaran et al., 2007).

Complications of Pregnancy

Adverse perinatal outcomes associated with cocaine use are believed to be largely due to the vasoconstrictive effects of cocaine on uterine blood supply (Woods et al., 1987). An increase in maternal mean arterial blood pressure, a decrease in uterine blood flow, and a transient rise in fetal systemic blood pressure after an intravenous cocaine infusion have been described in fetal sheep along with significant fetal hypoxemia associated with changes in uterine blood flow (Woods et al., 1987). Maternal hypertension and intermittent fetal hypoxia contribute to the higher risks for placental abruption and IUGR seen in cocaine-exposed infants (Pinto et al., 2010; Behnke et al., 2013).

To date, no well-defined cocaine-associated syndrome has been identified, and the teratogenic potential of cocaine remains controversial. Earlier reports had suggested that cocaine-exposed infants had a higher rate of limb reduction anomalies, heart defects, ocular anomalies, intestinal atresia or infarction, and other vascular disruption sequences. However, the preponderance of more recent data from multiple studies has failed to demonstrate higher rates of other congenital anomalies among cocaine-exposed infants (Behnke et al., 2013).

Women who use cocaine during pregnancy are at higher risk for stillbirths, spontaneous abortions, placental abruption, IUGR, anemia and malnutrition, and maternal death from intracerebral hemorrhage. Cocaine directly stimulates uterine contractions because of its α -adrenergic, prostaglandin, or dopaminergic effects, with resulting greater risk for fetal distress and premature deliveries. Placental abruption appears to be related to cocaine use only when the drug is used shortly before delivery (Ostrea et al., 1992). Cocaine use significantly increases the odds ratio (OR) for prematurity, low birth weight, premature rupture of membranes, and IUGR (Bada et al., 2002, 2005; Shankaran et al., 2007; Pinto et al., 2010).

Overall, because of the higher risks of premature delivery, the frequency of respiratory distress syndrome is greater in cocaine-exposed infants. Cocaine-exposed infants less frequently require surfactant administration and intubation for respiratory distress syndrome; however, the risks of bronchopulmonary dysplasia are similar in infants who have and those who have not been exposed to cocaine during gestation (Hand et al., 2001).

Fetal Growth

Infants exposed to cocaine in utero have lower birthweight, smaller birth length, and smaller head circumference (Bada et al., 2002, 2005; Pinto et al., 2010; Behnke et al., 2013). Cocaine is hypothesized to reduce fetal growth via vasoconstriction of uteroplacental vessels with consequent decreased fetal substrate and oxygen delivery (Schempf, 2007). Several studies have shown a dose-response effect of cocaine exposure on fetal growth. In the Maternal Lifestyle Study, cocaine-exposed infants were 1 week younger in GA, and after controlling for confounders, cocaine exposure was associated with decrements in birthweight (151 g), length (0.71 cm), and head circumference (0.43 cm) at 40 weeks' gestation (Shankaran et al., 2007). After adjusting for the effects of birthweight, GA, sex, maternal height, maternal weight gain, and other drug use, newborns with a high exposure to cocaine, as measured by radioimmunoassay of cocaine metabolites in maternal hair, had a disproportionately smaller head circumference even for their birthweight, resulting in “head wasting” (Bateman and Chiriboga, 2000).

Long-Term Effects of Perinatal Cocaine Exposure

No major neurologic deficits in motor development have been reported after in utero exposure to cocaine. Although infants exposed

to cocaine were reported to have lower motor skills at 1-month testing, they displayed significant improvements over time. Both higher and lower levels of tobacco use were related to poor motor performance (Shankaran et al., 2007).

Subtle neurobehavioral abnormalities have been reported in older studies and more recently using the NICU Network Neurobehavioral Scale (NNNS) to evaluate infants in the month after birth. Cocaine-exposed infants manifest a range of neurobehavioral abnormalities that were initially described as drug withdrawal but are more likely caused by acute intoxication. Signs are present at birth and wane as cocaine and the metabolite benzoylecgonine are cleared from plasma. The infants are hypertonic, irritable, and tremulous (Hudak et al., 2012), and they may have abnormal crying, sleep, and feeding patterns. Tachycardia, tachypnea, and apnea have been noted in two blinded, controlled studies, with significant elevations in cardiac output, stroke volume, mean arterial blood pressure, and cerebral artery flow velocity resolving by day 2, which is consistent with an intoxicant effect of cocaine (van de Bor et al., 1990a, 1990b). Cocaine-exposed infants may have abnormal electroencephalograms or clinical seizures, perhaps the result of toxicity from the metabolite benzoylecgonine; however, neonatal seizures attributable directly to maternal use of cocaine are rare (Legido et al., 1992).

Persistent behavioral, neurologic, and rearing problems have been reported in children exposed to both cocaine and opioids (Hunt et al., 2008). No significant differences in mean developmental scores were noted in a group of children exposed to cocaine plus polydrugs compared with a group without drug exposure. Other investigators reported no differences between infants who have and those who have not been exposed to cocaine in mean cognitive, psychomotor, or language quotients at age 36 months (Kilbride et al., 2000).

The neurodevelopmental problems among children exposed to cocaine may occur either from a direct teratogenic drug effect during gestation or from the effects of the social environment in which the developing infant is reared (Behnke et al., 2013). Singer et al. (2002) reported that cocaine-exposed infants are twice as likely to have significant cognitive but not motor delays at 2 years, and they demonstrated a downward trend in mean developmental scores by 2 years, which is consistent with a deleterious effect of the environment, parental stimulation, socioeconomic status, or possibly other, indirect effects of drugs on the developing CNS. Other studies have not consistently demonstrated this association (Frank et al., 2001). In contrast, the Maternal Lifestyle Study, after controlling for covariates, found no differences in Bayley scores between cocaine-exposed, opioid-exposed, and control infants for the first 3 years of life (Shankaran et al., 2007), although subtle effects on cognitive subscales were reported at 3 years (Messinger et al., 2004).

A more recent report of volumetric magnetic resonance imaging in thirty-five 12-year-old children exposed to cocaine in utero found smaller total parenchymal volumes, lower cortical gray matter volumes, and smaller head circumferences with prenatal substance exposure. The decreases were statistically significant only for prenatal cigarette exposure and for infants exposed to all substances studied (cocaine, tobacco, marijuana, and alcohol) (Rivkin et al., 2008). As in other studies, exposure to multiple substances clearly has more potential to have detrimental effects on the developing brain.

Amphetamines

History/Epidemiology

Amphetamines have surpassed cocaine as the primary illicit drugs used by pregnant women in many states. Methamphetamine (or

“crystal”) has been the primary form abused, because it can be produced locally and fairly cheaply. Greater restrictions on the importing of cocaine have also contributed to resurgence in amphetamine use. Amphetamines have always been popular among adolescents, especially females, and, accordingly, women of child-bearing age are at high risk for perinatal abuse. The Infant Development, Environment, and Lifestyle (IDEAL) study chose four major US cities with known methamphetamine-abusing populations and reported methamphetamine use in 5.2% of pregnant women. As in previous reports, these women frequently used other substances: 25% used tobacco, 22.8% used alcohol, 6% used marijuana, and 1.3% used barbiturates (Arria et al., 2006).

Pharmacology and Biologic Actions

Amphetamine (α -methylphenethylamine) was synthesized in 1887 and introduced in the United States in 1931. The *N*-methylated form, methamphetamine (or “crystal”), is increasingly abused because it readily dissolves in water for injection and it sublimates (converts directly from a solid to gas) when smoked (known as *ice*). The amphetamine isomers have similar clinical effects and can be distinguished only in the laboratory. Amphetamines were initially marketed for the treatment of obesity and narcolepsy and continue to be used for the treatment of attention deficit disorders in children. Amphetamines are classified as schedule II drugs, like cocaine and narcotics. Amphetamines are taken orally, inhaled, or injected. The clinical effects and toxicity of these agents are often indistinguishable from those of cocaine. The primary difference is in the duration of action. The psychotropic effects of cocaine are of a short duration, 5–45 minutes. The effects of amphetamines may last from 2–12 hours. Methamphetamine exposure has direct and indirect effects on the fetus, with increases in maternal blood pressure and restrictions in delivering nutrients and oxygen to the fetus (Smith et al., 2003). The clinical effects of amphetamines resemble those of cocaine. Like cocaine, amphetamines are sympathomimetics, and they potentiate the actions of norepinephrine, dopamine, and serotonin. In contrast to cocaine, amphetamines appear to exert their CNS effects primarily by enhancing the release of neurotransmitters from presynaptic neurons. Amphetamines can block reuptake of released neurotransmitters; they can also exert a weaker direct stimulatory action on postsynaptic catecholamine receptors.

Complications of Pregnancy

The medical and obstetric complications of amphetamine use are similar to those described for cocaine use. Amphetamine toxicity has been described as more intense and prolonged than cocaine toxicity. Visual, auditory, and tactile hallucinations are common, and microvascular damage has been seen in the brains of chronic users. Amphetamine withdrawal is characterized by prolonged periods of hypersomnia, depression, and intense, often violent paranoid psychosis. Obstetric complications include a higher incidence of stillbirth. Methamphetamine use is also associated with an increased incidence of premature delivery and placental abruption. Methamphetamine users who stop using earlier in gestation have rebound weight gain, suggesting that the anorexic effects are limited to continuous use (Smith et al., 2003). Like the pregnancies of cocaine users, the pregnancies of amphetamine users are characterized by poor prenatal care, sexually transmitted diseases, and cardiovascular problems including placental abruption and postpartum hemorrhage. The risk of cerebrovascular accidents is lower in pregnant amphetamine users than in pregnant cocaine users, but the mechanism for this difference is not understood.

Perinatal problems associated with maternal amphetamine use include prematurity and IUGR (Smith et al., 2006; Behnke et al., 2013). Fetal growth restriction, leading to smaller head circumference and lower birthweight, can result from the vasoconstrictive effects of norepinephrine or other vasoactive amines or from diminished maternal nutrient delivery as a consequence of the anorectic effect of amphetamine. Systemic effects from altered norepinephrine metabolism explain the transient bradycardia and tachycardia reported in exposed infants. Studies have failed to show consistent patterns of malformations in amphetamine-exposed infants, although several studies report cleft lip and cleft palate in association with amphetamine and methamphetamine exposure during early gestation (Behnke et al., 2013).

Fetal Growth

The IDEAL study followed 84 methamphetamine-exposed and 1534 unexposed infants (confirmed by screening for meconium). Both groups included alcohol, tobacco, and marijuana use but excluded opioids, PCP, and lysergic acid diethylamide (LSD) (Smith et al., 2003, 2006; Arria et al., 2006). Cocaine and methamphetamine use occurred together in 13% of the methamphetamine users, and tobacco, alcohol, and marijuana use were also more frequent in the methamphetamine users. Methamphetamine-exposed infants were 3.5-fold more likely to be SGA (less than the 10th percentile; 18% incidence). Methamphetamine contributed significantly to low birth weight, even after correcting for confounders such as low socioeconomic status, GA, and tobacco exposure.

Long-Term Effects of Perinatal Amphetamine Exposure

Early neurobehavioral changes have been associated with maternal methamphetamine use; heavy use was associated with lower arousal, increased lethargy, and increased CNS stress (Smith et al., 2008). However, a detailed analysis in a subgroup of the same population found that these same abnormalities on the NNNS were associated with maternal depression and that prenatal methamphetamine exposure was not associated with additional neurodevelopmental differences (Paz et al., 2009).

In methamphetamine-exposed infants, neurodevelopmental abnormalities have been described to persist as late as 14 years (Cernerud et al., 1996). Intellectual capacity does not appear to be diminished among exposed infants. These children are described as exhibiting disturbed behavior, including hyperactivity, aggressiveness, and sleep disturbances. Eriksson et al. (2000) reported that neurobehavioral abnormalities appear to be associated with the extent and duration of fetal exposure and with the severity of head growth restriction. In this study, children with the most severe problems were those born to mothers who abused amphetamines throughout pregnancy and were reared in homes with an addicted parent. Alterations in growth have been reported after prenatal exposure, with striking gender differences (Cernerud et al., 1996). Drug-exposed boys in Sweden were taller and heavier, and girls were smaller and lighter, than national standards. This finding suggests that fetal amphetamine exposure affects the onset of puberty, and amphetamines may interfere with neurodevelopment of the adenohypophysis. Children of amphetamine abusers appear to be at high risk for social problems, including abandonment, abuse, and neglect.

Selective Serotonin Reuptake Inhibitors

Prescribed medications can also have significant fetal and neonatal effects. The prevalence of depression during pregnancy is estimated

to be 14%–23%, and in the United States up to 13% of pregnant women use antidepressants during pregnancy (Yonkers et al., 2009). Selective serotonin reuptake inhibitors (SSRIs) are the most commonly prescribed antidepressants. They selectively inhibit reuptake of serotonin in presynaptic nerve terminals and increase the synaptic concentration of serotonin. They are better tolerated and have fewer side effects than tricyclic antidepressants because they do not affect other neuroreceptors (Lattimore et al., 2005). Animal studies have shown that serotonin appears as a neurotransmitter in the early fetal brain, but its role in development is not clearly delineated. Fluoxetine and its active metabolite cross the placenta and enter the fetal brain (Lattimore et al., 2005), although the significance of this finding is not known.

Studies of SSRI use in pregnant women have not shown any consistent pattern of malformations with first trimester use (Lattimore et al., 2005; Yonkers et al., 2009). There are no adverse pregnancy outcomes associated with SSRI use, including no evidence of growth restriction or increased fetal loss. Longer in utero exposure to antidepressants is more likely to result in earlier delivery, and low birth weight is increased (Lattimore et al., 2005; Yonkers et al., 2009).

The effects of maternal SSRI use, if any, are typically seen in the early neonatal period, with exposed infants being more likely to be admitted to an intensive care nursery. Poor neonatal adaptation is increased and includes tachypnea, irritability, jitteriness, hyper-tonia, sleep disturbance, temperature instability, poor feeding, hypoglycemia, and seizures. These neonatal symptoms are consistent with a gradual resolution of a hyper serotonergic state rather than a withdrawal syndrome and usually resolve spontaneously within the first 2 weeks (Lattimore et al., 2005; Moses-Kolko et al., 2005; Hudak et al., 2012). A small increase in risk for persistent pulmonary hypertension of the newborn has been associated with maternal SSRI use late in pregnancy (Huybrechts et al., 2015). A small study of neurodevelopment found possible motor effects in the first 18 months, but larger studies are needed (Lattimore et al., 2005; Yonkers et al., 2009).

Identifying Pregnancies and Babies at Risk

Pregnancies

Identification of perinatal substance abuse, in order to intervene and protect the health and well-being of both mother and child, has been a goal of practitioners for decades, ever since the scope of the problem became known – particularly for alcohol. Urine toxicology testing was initially believed to be the best approach, and the universal approach was used in many busy labor and delivery units, particularly in urban centers. In 1994, an ACOG Technical Bulletin concluded that urine toxicology testing had limited ability to detect substance abuse and therefore recommended against universal toxicology screening and for alternative screening methods. In 2003, the US Congress passed the Keeping Children and Family Safe Act. This law requires each state (as a condition of receiving federal funds under the Child Abuse Prevention and Treatment Act) to develop policies and procedures designed “to address the needs of infants born and identified as being affected by illegal substance abuse or withdrawal symptoms resulting from prenatal drug exposure.” This law included a requirement that healthcare providers notify child protective services regarding prenatal substance exposure but differed from the providers’ legal responsibility to report suspected child abuse or neglect because the former “shall not be construed to be child abuse” and “pregnant

women should not be punished for adverse perinatal outcomes” (Washington State Department of Health, 2016). Each state was expected to develop its own guidelines for identification of at-risk pregnancies. A 2015 ACOG Committee Opinion (2015a) stated that best practices included universal screening questions followed by brief interventions or referrals. A number of screening tools have been developed including T-ACE (tolerance, annoyed, cut down, eye-opener), TWEAK (tolerance, worried, eye-opener, amnesia, K/cut down), and 4Ps Plus (parents, partner, past, pregnancy + assess for substance abuse, domestic violence) (Chang, 2001; Chasnoff et al., 2005). Identification of at-risk pregnancies concentrated on the maxim “if you don’t ask, they won’t tell.” The universal use of standard screening questionnaires is strongly recommended for obstetricians (ACOG, 2011, 2012, 2015a). Therefore a history of drug and alcohol use should be routinely included in the initial contact with every pregnant patient. To be effective, the history taking must be nonjudgmental and must occur in the context of other lifestyle questions. When a positive history of use is obtained, intervention should begin immediately. The person taking the history should be prepared to offer preliminary counseling on risk reduction and concrete referrals for treatment programs, although access to drug programs is often restricted, inadequate, or delayed.

Although the screening questionnaire approach works well for women who seek prenatal care, it is not useful for the significantly higher percentage of substance-using pregnant women who do not seek or actively avoid prenatal care. For these women, it is more helpful to identify maternal risk indicators for perinatal substance abuse at the time of delivery. Use of one of the screening questionnaires, in addition to drug testing, increases the likelihood of identifying at-risk pregnancies and neonates, allowing for earlier referral for treatment or specialized interventions. Several of these maternal risk indicators for perinatal substance abuse were identified in the 2004 ACOG statement (Table 13.3) (ACOG, 2015a).

Babies

It is important for practitioners to know the difference between a substance-exposed newborn and a substance-affected newborn.

The Washington State Department of Health (2016) defines them as follows:

- Substance exposed:
 - tests positive for substances at birth *or*
 - mother tests positive for substances at time of delivery *or*
 - is identified by medical practitioner as having been prenatally exposed to substances
- Substance affected:
 - has withdrawal symptoms resulting from prenatal substance exposure *or*
 - demonstrates physical and behavioral signs that can be attributed to prenatal exposure to substances and is identified by a medical practitioner as affected

For the identification of either of these groups of infants, assessment of both maternal and newborn risk indicators (see Table 13.3) is essential. If risk indicators suggest perinatal substance abuse, then consideration should be given to newborn drug testing. For urine testing, there is a poor correlation between maternal and newborn tests. The earliest newborn urine will contain the highest concentration of substances, but the first urination may be missed and urine output in the first day is often scant. However, some drug metabolites such as cocaine are present for 4–5 days, and marijuana metabolites may persist for weeks. The disadvantages of newborn urine drug testing are that it primarily reflects substance exposure during the preceding 1–3 days, and alcohol is nearly impossible to detect. Meconium drug testing (at term) reflects substance exposure during the second half of gestation, has a high sensitivity for opioids and cocaine, and can assess for more drugs than urine testing. The cost is similar to newborn urine testing, but it generally takes longer to obtain results. Other newborn drug tests include hair – which is costly and has a high sensitivity for cocaine, amphetamines, and opioids but not for marijuana – and umbilical cord segments, which is an evolving technology that is becoming widely available and appears to reflect earlier exposure and gives results similar to meconium testing (Farst et al., 2011).

Pregnancy Management

Ideally, perinatal substance use or abuse should be identified by universal screening procedures during prenatal visits; this gives the practitioner an opportunity to intervene, with the goal being prevention of significant obstetric and neonatal complications related to substance abuse. Screening procedures and counseling should include the following topics:

Antepartum

- Initial screening for hepatitis, HIV, and tuberculosis (if not part of routine prenatal care) and ongoing screening for sexually transmitted infections
 - Referral to drug dependency/addiction treatment program, if appropriate
 - Discussion of possible drug effects on the fetus and newborn
 - Discussion of contraception and prevention of sexually transmitted disease
 - Discussion of breastfeeding issues related to alcohol and drug use
- ### Intrapartum
- Effects of recent drug use on labor and fetal well-being
 - Pain management (women in methadone or alternative opioid treatment programs will be less responsive to opioid pain medications)
 - Intrapartum prophylaxis for HIV and herpes simplex virus infections
 - Need for social services involvement

Postpartum

- Breastfeeding issues (related to both drug use and infection)
- Contraception and pregnancy prevention including tubal ligation
- Support for continuation in, or initiation of, a drug treatment program
- Child Protective Services notification

Maternal Treatment for Opioid Addiction

Methadone Maintenance

Methadone maintenance continues to be the primary treatment for opioid dependence. Potential benefits of maternal methadone maintenance are numerous and include the prevention of opioid withdrawal symptoms in the mother, better medical and prenatal care, improved health and growth of the fetus, and a decrease in both the use of illicit drugs and the potential for perinatal infections (ACOG, 2012). Methadone maintenance programs associated with comprehensive medical and psychosocial services for the pregnant woman are even more beneficial.

Detoxification of a pregnant heroin user is infrequently attempted because maternal drug withdrawal is believed to be associated with subsequent fetal withdrawal, fetal asphyxia, and spontaneous abortions (ACOG, 2012). In the United States, most pregnant, narcotic-addicted women are treated with daily methadone rather than a program of detoxification. Some authorities, however, have urged the reappraisal and reevaluation of the benefits of methadone maintenance in pregnancy.

In the Netherlands, women enrolled in a methadone program had higher rates of prenatal care, which were associated with higher birthweights and reduced prematurity in the offspring (Soepatmi, 1994). Others have shown that higher methadone doses are associated with improved head circumference and increased GA at delivery (Hagopian et al., 1996). Improved birthweights are believed to be to the result of a stable intrauterine environment uncomplicated by periods of intoxication and withdrawal, as well as less stress and better nutrition in the mother (ACOG, 2012).

Several investigators have found that neonatal withdrawal symptoms, birthweight, length of pregnancy, and the number of days infants require treatment for abstinence do not correlate with maternal methadone dosage (Cleary et al., 2010). Studying maternal and neonatal serum levels of methadone does not help clarify this dilemma. Investigators have found no correlation between neonatal serum levels of methadone and the maternal methadone dose at delivery, the maternal serum levels, or the severity of withdrawal symptoms in the neonates (Hudak et al., 2012). Other researchers have reported that neonatal signs of withdrawal correlate with the rate of decline of the neonatal plasma level during the first few days of life (Doberczak et al., 1993).

There are no definitive guidelines for methadone doses during pregnancy, and there is continuing controversy over the most appropriate dose of methadone maintenance during pregnancy. Current recommendations are to adjust the methadone dose to avoid withdrawal symptoms and decrease the likelihood of maternal use of illicit drugs (ACOG, 2012). High-dose methadone maintenance ranges between 60 and 150 mg/day. Medically supervised withdrawal from opioids in the pregnant women is not recommended due to high relapse rates (Jones et al., 2008b).

There is a growing body of literature promoting breastfeeding for infants of mothers in methadone maintenance programs as both beneficial and safe. Studies have shown that breastfed infants tend to have less need for pharmacotherapy for NAS, despite low

and unpredictable levels of methadone in breast milk and in infant serum. Maternal serum levels, breast milk levels, and infant serum levels do not correlate with maternal methadone dose (Jansson et al., 2008; Hudak et al., 2012).

Buprenorphine (Suboxone, Subutex)

Buprenorphine is an alternative opioid substitute that was first introduced in France in 1996. It is increasingly used instead of methadone for the treatment of opioid addiction because it has fewer autonomic side effects than methadone, lower risk of overdose, fewer drug interactions, and improved compliance and treatment efficacy (ACOG, 2012). Recent studies comparing methadone with buprenorphine in pregnancy found that both agents improve pregnancy outcome with decreased risk of growth restriction, abortion, preterm labor, and fetal death (Jones et al., 2010; Noormohammadi et al., 2016). Small randomized trials have compared methadone with buprenorphine treatment during pregnancy and found no difference in the neonatal outcomes (Jones et al., 2008a; Minozzi et al., 2008). The larger Maternal Opioid Treatment: Human Experimental Research (MOTHER) trial (Jones et al., 2010) found that although the infants exposed to buprenorphine or methadone were treated for abstinence syndrome at the same rate, infants exposed to buprenorphine received significantly lower total amounts of morphine and had a shorter hospital length of stay. The difference in length of stay was not significant after post hoc corrections for level of opioid dependence (Noormohammadi et al., 2016). A systematic review in 2014 concluded that risk of infant treatment for withdrawal, total morphine dose, and length of hospital stay were lower in infants of buprenorphine-treated women, but confounding variables contributed to these findings (Brogly et al., 2014). Disadvantages of buprenorphine use are the lack of long-term data on infant and child outcomes and increased patient dropout rate because of dissatisfaction with the drug effect. If a woman is well controlled on methadone before pregnancy, continued methadone maintenance is recommended (ACOG, 2012).

Human Immunodeficiency Virus and Other Viral Infections

Nationwide, intravenous drug abusers are the second largest risk group for HIV infection and the largest risk group for HCV infection. In the United States, other risk factors for HIV are multiple sexual partners. Since the mid-1990s, the rate of mother-to-child transmission has decreased significantly due to implementation of antenatal HIV testing and treatment during pregnancy, labor, and in the neonatal period. However, most mother-to-child transmission occurs during the intrapartum period, and there is a significant risk of transmission through breastfeeding (American Academy of Pediatrics Committee on Infectious Diseases, 2015b). Every infant born to a substance abuser should be evaluated for HIV infection, and universal precautions should be observed. The AAP Committee on Infectious Diseases (2015b) recommends rapid HIV testing of any mother whose HIV status is not known, with appropriate consent as required by local law. Many states have now adopted a policy promoting testing with an option to opt out, rather than requiring consent for testing (Branson et al., 2015).

Intravenous drug use places the woman at risk for multiple infectious complications, including cellulitis, thrombophlebitis, hepatitis, endocarditis, syphilis, gonorrhea, and AIDS. In a prospective study undertaken in Canada, a 5-year incidence of HIV seroconversion was 13.4%; the rate of conversion associated with injection of heroin or cocaine was 40% higher in women than in

men (Spittal et al., 2002). Opioid abusers are also less likely to receive prenatal care or to obtain late prenatal care (ACOG, 2012). Heroin-addicted mothers are often poorly nourished, have iron-deficiency anemia, and are hepatitis positive when compared with nonusers.

HCV is another chronic infectious condition that is spread by parenteral exposure to infected blood and can be acquired by the newborn in the perinatal period. The most common route for HCV infection of children is maternal-to-child transmission. The most common risk factors for adults acquiring infection are injection drug use or multiple sexual exposures in individuals with concomitant HIV infection. The 2015 AAP Red Book (American Academy of Pediatrics Committee on Infectious Diseases, 2015a) states that “seroprevalence [of HCV] among pregnant women in the United States has been estimated at 1% to 2%,” and the risk of perinatal transmission averages 5%–6% from women who are HCV-RNA positive at the time of delivery. Maternal coinfection with HIV has been associated with increased risk of perinatal transmission of HCV. Antibodies to HCV and HCV RNA have been detected in colostrum, but the risk of HCV transmission is similar in breastfed and bottlefed infants, so breastfeeding is currently allowed.

Neonatal Management After Gestational Substance Exposure

General

Although at higher risk for medical complications, the majority of infants of drug-using women do not require intensive neonatal care; however, symptomatic infants often need more nursing care. Physical examination on admission should document a GA assessment, birthweight, head circumference, and length. Infants should be examined carefully for evidence of malformations, dysmorphic facial features, or both. Studies such as electroencephalography and brain imaging may add diagnostic or prognostic information when physical or neurologic abnormalities are not consistent with drug exposure, but these procedures are not indicated for most drug-exposed infants. If indicated by neonatal or maternal risk indicators, toxicology testing should be performed on neonatal urine, meconium, and/or umbilical cord segments as soon as possible after birth. Infants whose mothers were not screened for HIV should undergo screening for perinatal HIV exposure and other infections such as hepatitis B, HCV, and syphilis, as clinically indicated. In some states, rapid testing of the newborn for HIV is “required by law if the mother refuses to be tested” so that appropriate treatment of the infant can be started before 12 hours of age. Rapid screening detects only HIV-1, the most common serotype of HIV in the United States, but it can miss HIV-2 (American Academy of Pediatrics Committee on Infectious Diseases, 2015a).

Cocaine-exposed infants weighing more than 1500 g have longer hospital stays and increased need for therapies, procedures, intravenous fluid, and formula feeding. These infants also undergo more investigations for sepsis, more NICU admissions, and more social and family problems delaying discharge (Bada et al., 2002). In the Maternal Lifestyle Study, cocaine-exposed infants had a higher frequency of infection (odds ratio [OR] 3.1, 99% confidence interval [CI] 1.8–5.4) and neurologic signs and symptoms (adjusted OR 1.7, 99% CI 1.0–2.1). Neurologic signs were highest in the infants exposed to opioids and cocaine but remained significantly increased in infants exposed to cocaine alone. Smoking also increased

the risk for neurologic signs and symptoms (Shankaran et al., 2007). The association between cocaine exposure and fetal hypoxic-ischemic episodes creates special concerns. Maternal cocaine use exposes infants to a higher than expected risk of problems with postasphyxial syndrome, and organ dysfunction from hypoxic-ischemic injury should be investigated and treated. Feedings in premature infants with cocaine exposure should be started cautiously, because premature infants exposed to cocaine may be at increased risk for necrotizing enterocolitis. In addition, after controlling for gender, GA, birthweight, maternal parity, ethnicity, and polydrug use, heavy cocaine use during pregnancy was associated with a slightly higher risk of subependymal hemorrhage (Shankaran et al., 2007).

Using the NNNS, subtle differences in behavior have been detected in drug-exposed newborn infants (Lester et al., 2002; Smith et al., 2008). Cocaine-exposed infants showed lower arousal, and with heavy cocaine use they showed lower regulation and higher excitability than did unexposed infants (Lester et al., 2002). There were no stress or abstinence signs associated with cocaine exposure. Marijuana use was associated with more stress and abstinence signs and higher excitability scores (Lester et al., 2002). Low birth weight was also significantly correlated with poorer regulation and higher excitability. Methamphetamine exposure was also associated with increased stress signs, especially in first-trimester use. Heavy methamphetamine use was related to lethargy, lower arousal, and increased physiologic stress (Smith et al., 2008). Neonatal neurologic abnormalities similar to a mild withdrawal syndrome, consisting of hypertonicity, irritability, and jitteriness, have been reported after in utero marijuana exposure but without documented evidence of long-term sequelae (Hudak et al., 2012). Finally, gestational nicotine exposure and SSRI exposure clearly alter the newborn neurobehavioral scores, and both have also been reported to elevate neonatal abstinence scores (Law et al., 2003; Godding et al., 2004; Moses-Kolko et al., 2005).

In the Maternal Lifestyle Study, only 100 women were identified as isolated users of opioids, and a similar number used cocaine and opioids. Transient but dramatic neurobehavioral signs are present in the first week of life as symptoms of opioid withdrawal (increased irritability, jitteriness, poor feeding, sweating, sneezing; Shankaran et al., 2007). See the discussion under Neonatal Abstinence Syndrome.

Breastfeeding and Drug Exposure

The AAP reaffirmed the many benefits of breastfeeding and the consumption of human milk in their 2012 policy statement on infant nutrition (American Academy of Pediatrics, 2012), and the World Health Organization (WHO) and CDC have set goals for increasing breastfeeding throughout the world. In the United States, the rates of breastfeeding have continued to rise. In the CDC’s recent breastfeeding report card, 79.2% of infants born in 2014 were breastfed; 49.4% were still breastfeeding by 6 months of age, with 18.8% still exclusively breastfeeding by 6 months (Centers for Disease Control, 2014b).

For women with substance use or misuse, whether licit or illicit, the choice to breastfeed is often challenging, and healthcare professionals are equally challenged in making recommendations. The known benefits of breastfeeding and human milk must be weighed against the potential risks to the infant, most of which are not well understood. There are many issues to consider, including lactation pharmacology issues, maternal behaviors that may be

dangerous during breastfeeding, coexisting risk factors or conditions, polydrug use/abuse, and infection risks. In addition, there are numerous infant factors to consider, including age and underlying medical conditions (including prematurity) that may affect drug clearance, accumulation, and/or toxicity.

The most current and comprehensive information regarding drug transfer to human milk, bioavailability, and potential toxicity are available on the Internet, at LactMed (<http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm>). For many drugs, this information is limited to data from animal studies, with uncertain relevance to human infants, or from anecdotal case reports. In addition, there are virtually no data regarding the many confounding factors (noted above) that probably increase the potential for adverse effects on the breastfeeding infant.

For infants whose mothers engage in active, ongoing use of “street” drugs (heroin, cocaine, methamphetamines, marijuana), the risks of breastfeeding outweigh any potential benefits. Use of street drugs is often associated with risky behaviors and poor maternal health and nutrition. In addition, illicit drugs are often mixed with dangerous adulterants and contain variable drug doses with a higher risk for drug overdose.

According to a recent survey, approximately half of breastfeeding women in Western countries consume alcohol, at least occasionally (Hastrup et al., 2014). Human milk alcohol levels generally parallel maternal blood alcohol levels. Heavy alcohol use during lactation has been associated with decreased milk production via interference with the milk ejection reflex. Studies evaluating infant effects of maternal alcohol consumption during breastfeeding have yielded mixed results, including mild effects on infant sleep. Women are generally advised to wait 90–120 minutes after consuming alcohol before breastfeeding (Reece-Stremtan and Marinelli, 2015).

Maternal smoking is not an absolute contraindication to breastfeeding, although there are measureable levels of nicotine and cotinine in breast milk. However, lactating women are encouraged to stop if they can, both for their own health and to minimize the detrimental effects of secondhand smoke on their infant – including the association with SIDS (American Academy of Pediatrics, 2013).

Smoking marijuana may similarly increase the risk of SIDS, and there is the added potential for infant harm resulting from nursing while “high.” THC, the psychoactive compound in marijuana, is also contained in cannabis edibles and medicinal compounds. It is lipophilic and excreted and concentrated in breast milk, absorbed by infants, and can be stored in fat tissues for weeks. As with most drugs, there are very limited data regarding the effects of THC exposure, via breast milk alone, on infant development. The data that do exist are conflicting and based upon studies done decades ago, when the potency of marijuana was substantially less than it is today (Reece-Stremtan and Marinelli, 2015).

Breastfeeding is now generally supported for women who are engaged in treatment for substance use disorders and who have had a confirmed period of abstinence (from street drugs) prior to delivery. Similarly, women who are dependent upon opioids for chronic pain or other conditions are encouraged to breastfeed if they are medically able and if their drug dosing is stable. Concentrations of methadone and buprenorphine in human milk are low, and there are other significant advantages for the mother and infant. This includes increasing evidence supporting a reduction in the severity and duration of NAS when mothers on methadone maintenance breastfeed and emerging evidence that the same is true for buprenorphine (Jansson et al., 2008; O’Connor et al., 2013; Welle-Strand et al., 2013).

Neonatal Abstinence Syndrome

The incidence of neonatal narcotic withdrawal, commonly termed NAS, has been steadily increasing in the United States and Canada, with prevalence rates of 3.6 to 5.1 per 1000 live births (2009–2011) and NICU admission rates up to 27 cases per 1000 admissions (Tolia et al., 2015; Davies et al., 2016).

Clinical Findings

Classic NAS occurs secondary to maternal use of morphine, heroin, methadone, buprenorphine, and other prescription opioid analgesics (e.g., oxycodone) and may be combined with withdrawal or effects from antidepressants (particularly SSRIs), anxiolytics, nicotine, and other substances (Hudak et al., 2012; Kocherlakota, 2014). Clinical signs consist of a wide variety of neurologic problems (tremors, hyperirritability, excessive crying, hypertonia, and, infrequently, seizures), gastrointestinal and feeding problems (diarrhea, hyperphagia, or poor feeding), autonomic signs of dysfunction (fever, sweating, and sneezing), and respiratory problems (Tables 13.4–13.5). These signs are most often related to gestational opioid exposure but are relatively nonspecific, with the differential diagnosis including infection, meningitis, hypoglycemia, hypocalcemia, hyponatremia, intracranial hemorrhage, seizures, and stroke (Hudak et al., 2012). The signs of neonatal serotonin syndrome (or SSRI withdrawal) may also mimic those of NAS (Moses-Kolko et al., 2005; Boucher et al., 2008).

The timing of withdrawal signs from specific drug exposures can often be anticipated; for example, heroin withdrawal usually occurs within 24 hours of birth, whereas methadone withdrawal typically begins later, at approximately 48–72 hours after birth. The incidence of NAS in infants born to women using heroin or methadone is high, with wide ranges reported between 16% and 90% (Jones et al., 2010), and between 30% and 91% of infants with signs of NAS receive pharmacologic treatment for NAS with inpatient stays averaging 3–5 weeks (Kuschel, 2007; Dryden et al., 2009). Premature infants generally have milder signs of withdrawal and often show alternating periods of hyperactivity and lethargy, with tremors seen less commonly.

TABLE 13.4 Clinical Signs of Neonatal Abstinence Syndrome

| | |
|---|--|
| Central nervous system dysfunction | Excoriation (from frantic movement) Hyperactive reflexes Increased muscle tone Irritability, excessive crying, high-pitched cry Jitteriness, tremulousness Myoclonic jerks Seizures Sleep disturbance |
| Autonomic dysfunction | Excessive sweating Frequent yawning Hyperthermia |
| Respiratory problems | Nasal stuffiness, sneezing Tachypnea |
| Gastrointestinal and feeding disturbances | Inadequate oral intake Diarrhea (loose, watery, frequent stools) Excessive sucking Hyperphagia Regurgitation |

TABLE 13.5 Neonatal Neurobehavioral Signs After Fetal Drug Exposure

| Drug | Onset (days) | Peak (days) | Duration | Relative Severity | Likely NICU Admission | Symptoms |
|--------------|--------------|-------------|----------------------------|-------------------|-----------------------|-----------------|
| Alcohol | 0–1 | 1–2 | 1–2 days (up to 18 months) | Mild | No | ? |
| Amphetamine | 0–3 | — | 2–8 weeks | Mild | No | Neuro |
| Barbiturates | 0–1 | 1–2 | 1–14 days | Mild to moderate | No | Neuro |
| Caffeine | 0–1 | 1 | 1–7 days | Mild | No | Neuro, Resp |
| Cocaine | 0–3 | 1–4 | ? months | Mild | No | Neuro |
| Heroin | 0–3 | 3–7 | 2–4 weeks | Mild to severe | Yes | Neuro, Resp, GI |
| Methadone | 3–7 | 10–21 | 2–8 weeks | Mild to severe | Yes | Neuro, Resp, GI |
| SSRI | 0–3 | 1–3 | 1–4 weeks | Mild to moderate | No | Neuro, Resp, GI |

A number of evaluation tools are used to assess the severity of opioid withdrawal after birth. Neonatal abstinence scores are scale-based using nursing observations of the severity of signs of withdrawal, and the modified Finnegan score is the most widely used scale (Finnegan, 1980; Hudak et al., 2012; Grim et al., 2013). Finnegan scoring requires rater training or else it is subject to wide inter-rater variability. Normal values for Finnegan scores in infants who have not been substance exposed have been reported; the 95%ile Finnegan score increases from 5.5 on day 1 to 7 on day 2, before decreasing to less than 6 from 48 to 72 hours (Zimmermann-Baer et al., 2010). The Lipsitz score was developed at the same time and is simpler to use, with a score greater than 4 indicating withdrawal. The Withdrawal Assessment Tool-1 was developed to monitor withdrawal from opioid infusions in pediatric intensive care units but is also used in some NICUs (Grim et al., 2013). The use of these scoring systems allows more objective quantification of the severity of the infant's withdrawal and the response to treatment. These scoring systems have shown good inter-observer reliability and can improve clinicians' ability to treat the withdrawing infant appropriately (Hudak et al., 2012; Grim et al., 2013).

The goal of medical management of opioid withdrawal is to avoid serious symptoms of NAS, such as seizures, and to maintain the infant's comfort while enabling the infant to feed, sleep, and gain weight in an appropriate manner. There are a number of reported threshold scores for initiating pharmacologic treatment (Finnegan NAS scores between 8 and 12) (Kuschel, 2007; Hudak et al., 2012; Kocherlakota, 2014), but none of these choices have been rigorously examined. The decision to begin treatment or to wean treatment should be influenced by the absolute score and other factors, such as the infant's age, comorbidities, other conditions leading to abnormal behavior, and a daily evaluation of the abnormal clinical elements observed in the scoring system (Kuschel, 2007). Standard medical practice is to combine both developmental and behavioral methods with pharmacologic interventions as necessary to control symptoms and signs of narcotic abstinence. Recent work has confirmed that use of a standard protocol for management of NAS decreases length of hospital stay and use of multiple drug therapy (Kocherlakota, 2014; Hall et al., 2015).

Treatment

Treatment for opioid withdrawal should always begin with supportive, nonpharmacologic measures such as swaddling, rocking, minimizing environmental stimulation, and avoiding unnecessary handling and irritation and should only progress to pharmacologic management when medically necessary. Breastfeeding is associated with less severe NAS, and mothers in a supervised drug treatment program should be encouraged to breastfeed and provide human milk (Hudak et al., 2012). Provision of adequate caloric intake for growth is essential as infants with NAS may require up to 150 kcal/kg per day to gain weight appropriately. Between 27% and 91% of infants exhibiting signs of NAS will receive pharmacologic treatment (Kocherlakota, 2014). The mainstay of treatment for opioid withdrawal is the use of opioids, either alone or in combination with other medications (Hudak et al., 2012; Grim et al., 2013; Kocherlakota, 2014). Medication is titrated for each infant according to the severity of the signs of withdrawal and abstinence scoring.

A 2006 survey in the United States showed that opioids, morphine or methadone, are the most common medication used for narcotic withdrawal, and phenobarbital is frequently used or added for polydrug exposure (Sarkar and Donn, 2006). A meta-analysis of seven studies found that opioid treatment reduced the time to regain birthweight and the duration of supportive care compared with supportive care alone; however, the length of hospital stay was increased (Osborn et al., 2005). Phenobarbital was also shown to be superior to diazepam for treating NAS, but small, randomized, controlled trials comparing morphine to phenobarbital for treatment of NAS suggested that opioids are superior at decreasing treatment duration and lowering NAS scores (Osborn et al., 2002; Jackson et al., 2004; Ebner et al., 2007).

A standard starting dose of morphine is 0.03–0.05 mg/kg given orally every 3–4 hours. This dose can be increased in increments of 0.03 to 0.1 mg until the symptoms are controlled. Daily doses of morphine for infants experiencing withdrawal at birth range from 0.024–1.3 mg/kg per day (Hudak et al., 2012). When the dose exceeds the 1.3 mg/kg per day, addition of a second drug is recommended (Kocherlakota, 2014).

Although preparations of oral morphine are most commonly used in recent studies, methadone is also reported as a treatment option (Kuschel, 2007; Kocherlakota, 2014). Methadone has a long duration of action and can be administered by either the oral or parenteral route. The initial recommended methadone dose is 0.05–0.1 mg/kg, followed by 0.025–0.05 mg/kg every 8–12 hours until symptoms are controlled. The long half-life of methadone makes it more difficult to titrate the dose, so once the symptoms are controlled, the total daily dose given is then divided into two doses and given every 12 hours (Kocherlakota, 2014).

In addition, sublingual buprenorphine has been reported as a treatment for NAS, but no large-scale studies are available (Kraft et al., 2011).

Phenobarbital has been used for signs of acute opioid withdrawal and is a frequently used second-line therapy for NAS, especially when maternal multidrug use is suspected (Kocherlakota, 2014). Phenobarbital does not, however, reduce significant physiologic signs of opioid withdrawal, such as diarrhea and seizures. At higher doses, phenobarbital has also been shown to impair infant sucking and cause excessive sedation. The doses of phenobarbital used are 5–20 mg/kg in the first 24 hours, followed by 2–4 mg/kg every 12 hours; the therapeutic blood level of phenobarbital for control of opioid withdrawal signs is not known. Combining an oral morphine solution and phenobarbital treatment was found to shorten duration of hospitalization and lessen the severity of withdrawal symptoms, compared with morphine treatment alone (Coyle et al., 2002, 2005). Compared with those treated with morphine alone, infants treated with morphine and phenobarbital were more interactive, had smoother movements, were easier to handle, and were less stressed. Dual treatment resulted in improved neurobehavioral organization during the first 3 weeks of life, which may indicate a more rapid recovery from opioid withdrawal (Coyle et al., 2005). A recent randomized clinical trial compared the addition of phenobarbital versus clonidine to morphine as a second-line therapy and found that the phenobarbital-treated infants had fewer morphine treatment days, with no difference in the cumulative total morphine dose. However, those infants were discharged home on phenobarbital therapy, from which they were slowly weaned over 1–8 months (Surran et al., 2013).

Clonidine, an α_2 -adrenergic receptor antagonist, is used in treating opioid withdrawal symptoms in older children and adults. In 2009, a randomized, controlled trial showed that adding clonidine to opioid treatment for NAS significantly reduced the number of treatment failures, the median length of opioid therapy, and the number of infants requiring high-dose opioids. There were reportedly no significant adverse events (i.e., hypertension, hypotension, bradycardia, or desaturations) related to clonidine use (Agthe et al., 2009). Surran et al. (2013) compared clonidine and phenobarbital as a second-line therapy for NAS in a randomized, single-center trial and found that clonidine was safe and efficacious. Infants treated with clonidine had more morphine treatment days and longer length of inpatient stay, probably due to inpatient weaning off clonidine. A recent randomized, controlled pilot study compared clonidine to morphine as first-line, single-drug therapy for NAS and found that morphine resulted in a significantly longer length of treatment. In addition, measurement of NNNS at 1 week and 2–4 weeks of age improved significantly with clonidine but not with morphine. One year follow-up did not show differences in motor, cognitive, or language scores between the treatments (Bada et al., 2015). Before clonidine begins to be more widely used for NAS, a larger clinical trial is indicated to investigate appropriate dosing regimens and determine long-term safety.

Once medications have been titrated to a level that controls the severity of opioid withdrawal and lowers the withdrawal scores, then tapering of the dosage should be started. A common method is to decrease the opioid dose by 10%–20% of the highest dose, either daily or every other day, with continued surveillance of withdrawal scores to assure the infant tolerates the decrease. It is not unusual to note increased signs of opioid withdrawal during the medication tapering. The goal of weaning is to allow infants to acclimate to a new and lower dose of medication while ensuring that they are comfortable and consolable and are able to sleep, eat, and gain weight appropriately. Objective measurements using established withdrawal scoring systems should be used to determine the rate and efficacy of medication tapering (Kocherlakota, 2014). Whether narcotics can safely be weaned more rapidly in infants has not been studied. One small study reported good results using oral morphine on an as-needed basis for elevated individual withdrawal scores, rather than providing regular doses of morphine every 3–4 hours (Ebner et al., 2007). Clonidine must be carefully weaned in the hospital because of the risk of rebound autonomic activity with possible hypertension and tachycardia; recent studies have proposed stepwise clonidine weans (Surran et al., 2013; Bada et al., 2015).

The average length of hospital stay for infants with NAS who are treated with medications varies from 8–78 days, with a stay of 21–30 days being common (Kuschel, 2007; Ebner et al., 2007; Bada et al., 2015). Investigation of outpatient management of detoxification may result in a shorter hospital stay, but with a more prolonged duration of neonatal treatment (Kuschel, 2007).

Similar principles apply to management of acquired or iatrogenic opioid and benzodiazepine dependency due to more prolonged need for these medications in some chronically ill NICU patients. Use of a withdrawal score should be implemented as soon as opioid doses are decreased. If there are signs of significant withdrawal, medication can be weaned more gradually over days to weeks (Hudak et al., 2012).

Prevention and treatment of NAS are areas where additional research is urgently needed, to define optimal treatment protocols, to improve care of both mothers and their infants, and to improve infant outcomes (McLemore et al., 2013; Jones and Fielder, 2015). There are preliminary reports of decreased regional brain volumes in neonates with NAS (Yuan et al., 2014). Improved neurodevelopmental and psychobehavioral follow-up is needed to identify long-term problems and needed services (Kocherlakota, 2014). Infants treated for NAS have been reported to have increased rates of rehospitalization during childhood for maltreatment, trauma, and mental and behavioral disorders, emphasizing the need for continued support of this group (Uebel et al., 2015).

Sudden Infant Death Syndrome

The incidence of SIDS was previously thought to be higher in cocaine-exposed infants, with a metaanalysis of 10 studies demonstrating a 4.1 OR for SIDS among cocaine-exposed infants (Fares et al., 1997) compared with infants not exposed to perinatal drugs. However, after data were controlled for concurrent use of other drugs, the increased risk for SIDS could not be attributed to intrauterine cocaine exposure alone but was believed to be caused by exposure to other illicit drugs and smoking. A recent analysis of exposed infants showed no association of maternal recreational drug use with SIDS but found an increase in SIDS associated with paternal marijuana use around the time of conception and during pregnancy (Klonoff-Cohen and Lam-Kruglick,

2001). Maternal alcohol use has also been associated with an increased risk of SIDS (O'Leary et al., 2013a).

There is a significant relationship between exposure to tobacco smoke and SIDS. A higher risk for SIDS is reported in infants exposed to maternal smoking with either antenatal or postnatal exposure (Salihu and Wilson, 2007). Additional evidence supporting a causal role includes a dose-response relationship (Rogers,

2008). With recent substantial decreases in SIDS risk (after “back to sleep”), maternal smoking is calculated to account for an increasing proportion of SIDS risk. Mitchell and Millerad (2006) suggest that one-third of all SIDS deaths might be prevented by eliminating in utero exposure to maternal smoking. Despite the increased risks of SIDS among drug-exposed and tobacco-exposed infants, home apnea monitoring is not indicated in the absence of other risk factors.

Summary

The magnitude of observed perinatal outcomes after illicit maternal substance use pales in comparison to the established health and developmental risks associated with tobacco, alcohol, and prescribed opioid exposure (Schempf, 2007). The greatest impact of illicit substance use may be the increased postnatal risks of

neglect, maltreatment, and disruptions in the home environment. Health policy must be directed at reducing all these complex factors associated with perinatal substance abuse and providing support for families and children with in utero substance exposure.

Antepartum Fetal Assessment

CHRISTIAN M. PETTKER AND KATHERINE H. CAMPBELL

KEY POINTS

- Fetal ultrasound assessment in the first, second, and third trimesters
- Antepartum fetal testing in high-risk pregnancies (nonstress test, amniotic fluid volume, biophysical profile, Doppler velocimetry)

A primary objective of obstetric care is the assessment and prevention of adverse fetal and neonatal outcomes. Maternal care is an integral step toward this goal. Optimization of the maternal state, through monitoring and treatment of chronic conditions such as diabetes or hypertension or acute states like preeclampsia or preterm labor, is one important facet of care to achieve desirable perinatal outcomes. Monitoring and management of the fetus, although a more obvious step toward this goal, is somewhat less straightforward. Fetal assessment demands a view into the somewhat inaccessible intrauterine environment. Our ability to gain access to this space to gauge the needs and health of the fetus has improved dramatically with developments in technology and increased understanding of fetal physiology over the past three decades. As a result, perinatal morbidity and mortality have decreased considerably over that time (Fig. 14.1).

In general, antepartum fetal assessment utilizes various techniques to assess fetal health and well-being in pregnancies that are at increased risk of fetal death due to preexisting maternal conditions (chronic hypertension) or pregnancy-related complications (fetal growth restriction [FGR]). Selecting appropriate patients at risk for adverse perinatal events can enhance the prediction of these events, although some tests may be appropriate even for a low-risk population. The assessment may allow for certain therapeutic options – often, timely delivery – to prevent fetal harm. The overall goal of these efforts is to reduce perinatal mortality, although the reduction of morbidities such as cerebral palsy or preventable birth injury is intertwined with this objective. In antenatal assessment in the third trimester, the prediction and detection of fetal acidemia and hypoxemia form a central principle underlying these efforts.

It is important to make the distinction between antepartum and intrapartum fetal assessment: the latter is specifically related to monitoring the fetus during labor. The nature of labor affords certain advantages (e.g., dilation allows blood samples from the fetus) and restrictions (the lack of fluid after rupture of membranes

creates difficulties for ultrasound examination) that do not occur in the antenatal period. As a result, this chapter focuses only on events and assessment preceding labor.

General Principles

Principles of Testing

Many of the tests used for antepartum fetal assessment are screening tests that will lead to further testing allowing for diagnosis and decision making; therefore it is important to note the principles guiding such tests. The outcome, principally perinatal morbidity and mortality, is a significant burden to both the individual and the overall healthcare system. The primary tools for assessment, ultrasound examination and fetal heart rate (FHR) monitoring, are generally easy, safe, and acceptable to patients. Screening has the potential to allow important and timely interventions, such as antenatal steroid administration or delivery. The predominant difficulty with fetal testing comes in the unproven utility of testing to improve outcomes. Furthermore, some tests, such as the nonstress test (NST), have high false-positive rates; therefore when used as a diagnostic test (e.g., to decide on delivery), they can lead to the overuse of interventions. The specificity and sensitivity of the tests vary, and the critical step to enhancing test performance is patient selection. The utility of fetal surveillance involves the judicious application of the tests in patients with specific risk profiles.

Fetal Physiology and Behavior

The first trimester (≤ 14 weeks' gestation) is mainly a time of system development and organogenesis. The hyperplastic enlargement during the first 11 weeks produces standard rates of growth, with deviation being rare. At the completion of the first trimester, the major organ systems have developed, allowing the opportunity during the second trimester to assess for anomalies in development. The second and third trimesters involve maturation of these systems. Fetal assessment, primarily performed in the third trimester, is concerned with the prediction or detection of fetal hypoxemia and acidemia. Integration of the fetal neurologic and cardiovascular systems as they relate to acid–base status is the cornerstone of this assessment. By the beginning of the third trimester, there is usually adequate maturation present in the neurologic and cardiovascular

• **Fig. 14.1** Fetal and Infant Mortality Rates in the United States, 1990–2012. Infant mortality rates are the number of infant deaths per 1000 live births. Fetal mortality rates are the number of fetal deaths of 20 weeks' gestation or later per 1000 live births and fetal deaths. (From CDC/NCHS, National Vital Statistics System.)

systems to enable meaningful fetal assessment. We are thus able to monitor the manifestations of hypoxemia and acidemia as shown by neurologic and cardiovascular changes. In pregnancies at extremely high risk for adverse perinatal outcome or stillbirth, fetal assessment may be performed in the second trimester, as early as 24 weeks' gestation.

Technology

The technologic underpinning of fetal assessment is ultrasound. FHR monitoring during the antepartum period depends on a Doppler cardiogram; movements of the fetal heart, in particular the sounds of the valves, are detected by this monitor. The time between the beats is translated into a heart rate, which is then graphically represented on a chart over time. This process produces the FHR monitoring strip that becomes the NST or contraction stress test (CST).

Contemporary ultrasound imaging technology involves a wide array of features, including B-mode (basic imaging), M-mode (mapping the movement of structures over time), pulsed Doppler (demonstrating flow velocity in a particular area, such as a vessel), color Doppler (showing intensity and direction of flow through shades of red and blue), and power Doppler (a more sensitive form of colorized Doppler). Magnetic resonance imaging (MRI) is often used to supplement ultrasound imaging, especially for imaging of the fetal brain.

Indications and Timing

Most fetal testing protocols involve a stepwise approach, and the first step is the selection of the appropriate patient. Suggested assessments for low-risk pregnancies include one ultrasound examination for dating and one for the basic anatomic survey. Prenatal risk assessments for chromosomal disorders, such as first-trimester risk assessment with maternal serum analysis and fetal nuchal translucency assessment, cell-free fetal DNA analysis, or the second-trimester maternal quadruple serum screen, are additional options (see Chapter 18 for additional discussion of these tests). Whereas up to 30% of perinatal morbidity may occur in low-risk patients, routine fetal testing beyond that described previously in a low-risk pregnancy is an ineffective use of resources.

High-risk pregnancies are those at greater peril for perinatal morbidity and mortality. These pregnancies often have more justification for targeted or detailed anatomic ultrasound examinations

• BOX 14.1 Common Indications for Antepartum Fetal Assessment: High-Risk Pregnancies

Fetal

- Abnormal fetal testing, fetal distress
- Decreased fetal movement
- Fetal growth restriction
- Monochorionic multiple gestation
- Oligohydramnios

Maternal–Fetal

- Placenta abruption (abruptio placenta)
- Alloimmunization
- Late term or postterm pregnancy
- Gestational hypertension or preeclampsia
- Gestational diabetes
- History of fetal death

Maternal

- Advanced maternal age (>40 years old)
- Cyanotic cardiac disease (severe)
- Hypertension, chronic
- Morbid obesity
- Pulmonary disease (severe)
- Chronic renal disease
- Systemic lupus erythematosus
- Hyperthyroidism

and for regular assessment of fetal growth or heart rate assessment. Common conditions requiring increased fetal surveillance are shown in Box 14.1.

Pregnancy dating should be confirmed at the earliest possible moment, and fetal anatomic screening is best accomplished in the second trimester, specifically at 18–20 weeks' gestation, when visualization of the anatomic features is adequate. However, standards for the timing of antepartum fetal assessment to survey for fetal compromise do not exist. Certainly, assessment with NST or biophysical profiles would have little utility before viability (approximately 24 weeks' gestation). Guidelines for initiating fetal testing for specific indications are largely based on the risk of fetal loss at a particular gestational age (GA). Most fetal testing algorithms begin antepartum fetal testing no earlier than 32 weeks' gestation. However, the most at-risk pregnancies may be monitored at earlier GAs when delivery would be considered for fetal benefit.

Fetal Assessment in Low-Risk Pregnancies

Ultrasound: Pregnancy Dating

The *estimated date of delivery* is defined at the beginning of pregnancy based on the best available information, including menstrual history, ultrasound data, and assisted reproduction technology. The median duration of a singleton pregnancy is 280 days (40 weeks) from the first day of the last menstrual period or 266 days (38 weeks) from the time of ovulation. *Term* is defined as 37 to 41 + 6 weeks' (259–294 days) gestation. This definition is further broken down in the subgroups: early term (37 weeks 0 days – 38 weeks 6 days), late term (41 weeks 0 days – 41 weeks 6 days). Preterm is defined as delivery prior to 37 weeks. This definition is further broken down into the subgroup late preterm (34 weeks 0 days – 36 weeks 6 days). Postterm pregnancies are defined as delivery at 42 weeks and beyond (Box 14.2). Given that the preterm and postterm

• BOX 14.2 Definition of Gestational Age Categories

Gestational Age Categories

| | |
|--------------------------|-----------------------|
| Term Pregnancy | 37 + 0 – 41 + 6 weeks |
| • Early term | 37 + 0 – 38 + 6 weeks |
| • Late term | 41 + 0 – 41 + 6 weeks |
| Preterm Pregnancy | <37 weeks |
| • Late preterm pregnancy | 34 + 0 – 36 + 6 weeks |

periods are associated with increased risks to the fetus and newborn, pregnancy dating provides an approximate expectation for the completion of the pregnancy and serves as a basis for the efficient and appropriate use of fetal surveillance, testing, and treatment. Accurate pregnancy dating by ultrasound has been associated with reduced diagnoses of growth restriction (Waldenström et al., 1992), reduced use of tocolysis for preterm labor (LeFevre et al., 1993), and a reduced need to intervene in postterm pregnancies (Neilson, 2000; Whitworth et al., 2015). Additionally, early ultrasound assessment is associated with increased diagnosis of multifetal pregnancies (Whitworth et al., 2015).

In a spontaneous pregnancy in a woman with regular cycles and normal menstrual periods, the last menstrual period is often an accurate way of dating a pregnancy. Menstrual dating is less accurate in women who are taking oral contraceptives, were recently pregnant, or have irregular periods or intermenstrual bleeding. In these cases, and others in whom there is uncertainty, ultrasound dating in the first trimester is accurate and effective. A fetal pole may be seen beginning at 6 weeks' gestation, and the fetal heartbeat should be visualized by 6 to 7 weeks' gestation (Doubilet et al., 2013). In the first trimester, measurement of the crown-rump length is accurate to within 5 to 7 days; therefore this measurement should take priority in dating a pregnancy when the timing of the last menstrual period suggests a GA outside this range of variation (Robinson and Fleming, 1975; Drumm et al., 1976; Savitz et al., 2002; American College of Obstetricians and Gynecologists [ACOG], 2014a). A first-trimester ultrasound examination is indicated to confirm an intrauterine pregnancy (i.e., exclude ectopic pregnancy), confirm fetal viability, document fetal number, and estimate GA. During this ultrasound, the maternal pelvis and ovaries may be assessed to look for the presence of abnormalities, including uterine fibroids and Müllerian anomalies and ovarian masses, such as a dermoid cyst. In the second trimester, ultrasound dating is less accurate (discrepancy from 7 to more than 14 days) but can nonetheless be helpful. Measurement of the biparietal diameter (BPD) of the fetal head, the most accurate parameter, can be accurate to within 7 to 10 days (Campbell et al., 1985; Waldenström et al., 1990). The BPD is also a parameter of choice because it is less affected by chromosomal anomalies, in particular Down syndrome (Cuckle and Wald, 1987). Usually in the second or third trimesters, several biometric measurements – such as BPD, head circumference, abdominal circumference (AC), and femur length – are recorded, and a computerized algorithm can generate an estimated GA. Additional fetal measurements, including other fetal long bones (i.e., humerus, ulna, and tibia) and transverse cerebellar diameter may also assist with estimating fetal GA (Goldstein et al., 1987; Melamed et al., 2009).

Ultrasound: Second and Third Trimesters

Perinatal ultrasound examination in the second and third trimesters can be classified broadly into three types: the basic or standard

examination, the specialized (detailed) examination, and the limited examination. The standard or basic examination includes the determination of fetal number, fetal viability, fetal position, fetal biometry, placental location, amniotic fluid volume, the presence or absence of a maternal pelvic mass, and the presence of gross fetal malformations (ACOG, 2009) (Box 14.3). Most pregnancies can be evaluated adequately by this basic examination. If the patient's history, physical examination, or basic ultrasound examination suggests the presence of a fetal malformation, a specialized or detailed examination should be performed by a sonographer who is skilled in fetal evaluation. During a detailed ultrasound, which is best performed at 18 to 20 weeks' gestation, fetal structures are examined in detail to identify and characterize any fetal malformation. In addition to identifying structural abnormalities, a specialized ultrasound examination can identify sonographic markers of fetal aneuploidy. In some situations, a limited examination may be appropriate to answer a specific clinical question (such as fetal viability, amniotic fluid volume, fetal presentation, placental location, or cervical length) or to provide sonographic guidance for an invasive procedure (such as amniocentesis).

Current debate centers on who should undergo sonographic examination and what type of evaluation these patients should have. Advocates of routine sonography cite several advantages of universal ultrasound evaluation, including more accurate dating of pregnancy and earlier and more accurate diagnosis of multiple gestation, structural malformations, and fetal aneuploidy (discussed

later in [Ultrasound](#) section). Opponents of routine sonographic examination argue that it is an expensive screening test (\$100–\$250 for a standard examination) and that the cost is not justified by published research, which suggests that routine ultrasound examinations do not significantly change perinatal outcome ([Ewigman et al., 1993](#); [LeFevre et al., 1993](#); [Crane et al., 1994](#)). However, subsequent cost–benefit analyses regarding the routine use of ultrasound in low-risk pregnancies have concluded both cost savings ([Vintzileos et al., 2000](#)), if the ultrasound is performed in a tertiary care setting, and net loss, if the ultrasound is performed by less-experienced providers. Ultrasound performed in a country with socialized medicine proved cost saving ([Leivo et al., 1996](#)). Thus it may be the more-tempered approach to ultrasound screening with utilization of highly skilled sonographers and sonologists that allows the routine ultrasound screening of pregnancies be both effective and economical. Nonmedical use of obstetric ultrasound is not supported by either ACOG or the American Institute of Ultrasound in Medicine (AIUM) for many reasons, including the potential for false reassurance at the time of the ultrasound as well as no formal process for follow-up if an abnormality is identified ([ACOG, 2004](#)).

Second-trimester ultrasound examination may be indicated for various reasons, including uncertain dating, uterine size larger or smaller than expected for the estimated GA, vaginal bleeding, suspected multiple gestation, a medical disorder that can affect fetal growth and development (e.g., diabetes, hypertension, collagen vascular disorder), a family history of an inherited genetic abnormality, a suspected fetal malformation or growth disturbance, or suspected fetal death ([ACOG, 2009](#); [AIUM, 2013](#)). In the United States, most patients undergo a standard examination at 18 to 20 weeks' gestation to screen for structural defects. An understanding of normal fetal physiology is critical to the diagnosis of fetal structural anomalies. For example, extra-abdominal herniation of the midgut into the umbilical cord occurs normally in the fetus at 8 to 12 weeks' gestation and can be misdiagnosed as an abdominal wall defect. Placental location should be documented with the bladder empty, because overdistension of the maternal bladder or a lower uterine contraction can give a false impression of placenta previa. If placenta previa is identified at 18 to 22 weeks' gestation, serial ultrasound examinations should be performed to follow placental location. Presence of placenta previa at 15–17 weeks has about a 12% risk of being present at term, while presence later in the second trimester (24–27 weeks) confers a 49% risk of persistence at term ([Dashe et al., 2002](#)). The umbilical cord should also be imaged, including the number of vessels and its fetal and placental insertion.

The indications for third-trimester ultrasound examination are similar to that for second-trimester ultrasound. Fetal anatomy survey examinations and estimates of fetal weight become less accurate as GA increases, especially in obese women or in pregnancies complicated by oligohydramnios. However, fetal biometry and an anatomic survey should still be performed, because certain fetal anomalies, such as achondroplasia, may become evident for the first time later in gestation.

Fetal Movement Counting

Fetal movement (quickening) is typically perceived by the mother at 16 to 22 weeks' gestation. Fetal hypoxemia is typically associated with a reduction in fetal activity; the fetus is essentially conserving energy and oxygen for vital activities. A typical procedure for fetal movement counting consists of having the patient record the interval

taken to feel 10 fetal movements, usually after a meal when the fetus is more active. If 10 movements are not detected in 1 hour, further testing is often recommended. The data supporting fetal movement counting are mixed. A large international cluster randomized trial involving more than 68,000 patients demonstrated no benefit ([Grant et al., 1989](#)), and a Cochrane analysis found insufficient evidence to support this technique to prevent stillbirth ([Mangesi and Hofmeyr, 2007](#)). However, a more recent Norwegian study found a significant reduction in the number of stillbirths without a subsequent increase in the number of hospital visits for decreased fetal movement when a standardized approach to patient education regarding the recommended approach to decreased fetal movement ([Tveit et al., 2009](#)) was implemented. Fetal movement counting represents a low-technology screening test that can be applied easily to all pregnancies. Although its effectiveness in improving perinatal outcomes is debatable, it can be used as a cost-effective first-line strategy.

Fetal Assessment in High-Risk Pregnancies

Cardiotocography

Cardiotocography is the visual representation of FHR and uterine contractions. FHR has been recognized as an important indicator of fetal status since the 19th century, with Lejumeau Kergaradec of Switzerland being credited with the first accounts of direct fetal auscultation and the uterine soufflé in 1821. FHR monitoring is based on the principle that the fetal neurologic system, through its afferent and efferent networks, serves as a key mediator to demonstrate fetal well-being. Oxygenation, acidemia, and other vital functions are monitored by peripheral chemoreceptors and baroreceptors, which provide input on fetal status through afferent neurologic networks to the central nervous system (CNS). This information is processed by the CNS, and signals are conducted through efferent networks to produce peripheral changes, particularly to the heart via direct parasympathetic vagal neurons, direct sympathetic signals, or indirect sympathetic stimulation of catecholamine release. In this way, fetal cardiac activity can be seen as a surrogate for fetal oxygenation and acid–base status.

For many years, assessment of the FHR was limited to the fetoscope, a direct stethoscope attributed to Adolphe Pinard in 1876. In 1957, Orvan Hess and Ed Hon at Yale University (New Haven, CT) introduced electronic FHR monitoring as a window into the status of the fetus ([Hon and Hess, 1957](#)). This technology relied on direct monitoring through a scalp electrode; only years later would Doppler technology allow cardiac signals to be detected noninvasively. FHR monitoring became a tool for fetal assessment, as it was recognized that certain FHR patterns were associated with fetal compromise and poor fetal outcomes.

The basic elements of a FHR strip are baseline, variability, accelerations, and decelerations. A baseline of 110–160 beats per minute is normal. Variability is determined by the irregular fluctuations in amplitude and frequency in the baseline, and variability of fewer than 6 beats per minute is often abnormal. Accelerations are classified as visually apparent abrupt increases that peak at 15 beats per minute or more above the baseline and last 15 seconds or longer. Fetal movements often coincide with FHR accelerations. Finally, decelerations, often classified as early, variable, or late, are decreases in the FHR that have specific pathologic and physiologic associations. Although primarily focused on intrapartum monitoring, the 2008 National Institute of Child Health and Human Development workshop report on fetal monitoring provides an excellent

• **Fig. 14.2** A Normal Nonstress Test. Note two fetal heart rate accelerations exceeding 15 beats/min and lasting at least 15 seconds during the monitoring period. FHR, Fetal heart rate.

summary of the nomenclature and interpretation involved (Table 14.1) (Macones et al., 2008).

Nonstress Test

A normal result of an NST is defined as a 20-minute FHR tracing that contains two heart rate accelerations lasting 15 seconds or longer that peak 15 beats or more above the baseline: often this is called a *reactive NST* (Fig. 14.2). Modifications are made in reference to GA. NSTs for fetuses at less than 32 weeks' gestation are often considered reactive if the acceleration is 10 beats per minute or more above the baseline and lasts for at least 10 seconds (Glantz and Bertoia, 2011; Cousins et al., 2012). Furthermore, to account for the periodicity of 20–30-minute sleep cycles in the fetus, an NST that is not reactive over the first 20 minutes may be continued an additional 20–40 minutes. A nonreactive NST or an NST with specific abnormalities (e.g., high or low baseline, decelerations) should be followed by a biophysical profile (BPP). It is important to note that some abnormal states, such as a fetal CNS abnormality or maternal drug ingestion, may contribute to a nonreactive NST. In these cases, ultrasound examination may provide appropriate information to determine the diagnosis or required management.

Falsely normal NSTs occur at a rate of 3–5 per 1000 tests, although this does not account for a baseline rate of unpreventable fetal deaths (Freeman et al., 1982b). The difficulty with the NST really lies in its lack of specificity for fetal death or compromise; the false-positive rate may be as high as 50% (Freeman et al., 1982b).

The rather modest false-negative rate is likely because of the NST being a measurement of short-term hypoxemia. Indeed, longer-term fetal status can be measured through amniotic fluid assessment, because the amniotic fluid is correlated with fetal urinary output, which is a surrogate for renal perfusion. When combined with an assessment of amniotic fluid level, the false-negative rate

of the NST is reduced to 0.8 per 1000, although a 60% false-positive rate remains (Miller et al., 1996). Thus when the amniotic fluid level is combined with the NST – sometimes known as the *modified biophysical profile* – the risk of fetal death is reduced to negligible levels in high-risk populations (Clark et al., 1989). For these reasons, the modified biophysical profile is a modality of choice for monitoring the high-risk pregnancy.

Contraction Stress Test

The CST assesses the FHR response in the presence of contractions. This test improves on the specificity and sensitivity of the NST by assessing the fetal response to stress. In fact, the CST preceded the NST, although the NST became more favorable because of fewer contraindications, ease of administration, and reduced time and supervision necessary. Compared with the NST, there is a much lower incidence of falsely normal tests (0.4 per 1000), representing an eightfold reduction in the risk of fetal loss in one study (Freeman et al., 1982a).

Contractions are stimulated by the administration of intravenous oxytocin or through maternal nipple stimulation. Of course, the CST is contraindicated in patients in whom contractions should not be provoked, such as threatened preterm delivery or preterm premature rupture of membranes, prior classical cesarean delivery, or placenta previa. A minimum of three contractions over a 10-minute period of continuous FHR assessment are necessary for a satisfactory test interpretation. An unsatisfactory test should be followed by continued testing with a modification of the mode of contraction stimulation. A negative (i.e., normal) test result demonstrates no late decelerations, whereas a positive test result shows late decelerations after 50% or more of contractions (Fig. 14.3). A positive test result requires immediate further testing or evaluation, if not delivery. An equivocal test demonstrates late decelerations with less than 50% of contractions and requires further testing or monitoring. A test that encompasses a hyperstimulatory

TABLE 14.1 Interpretation of Antepartum Cardiotocography

| Term | Characteristic | Description |
|--------------|----------------|--|
| Baseline | Definition | Mean FHR, rounded to increments of 5 beats/min (e.g., 140, 145); need baseline duration of ≥ 2 min during a 10-min segment, between periodic or episodic changes, to determine baseline |
| | Bradycardia | <110 beats/min for >10 min |
| | Tachycardia | >160 beats/min for >10 min |
| Variability | Definition | Fluctuations of the baseline heart rate; measured from peak to trough |
| | Absent | Undetectable |
| | Minimal | Undetectable to ≤ 5 beats/min |
| | Moderate | 6–25 beats/min |
| | Marked | >25 beats/min |
| Acceleration | Definition | Abrupt increase ≥ 15 beats/min lasting ≥ 15 s |
| | Prolonged | ≥ 2 min and <10 min (≥ 10 min is a baseline change) |
| Deceleration | Definition | Decreases in the FHR |
| | Variable | Abrupt decrease onset to nadir <30 s; decrease ≥ 15 beats/min lasting ≥ 5 s to <2 min |
| | Early | Gradual decrease onset to nadir ≥ 30 s with contraction |
| | Late | Gradual decrease onset to nadir ≥ 30 s; nadir of deceleration occurring after peak of contraction |
| | Prolonged | Decrease ≥ 15 beats/min lasting ≥ 2 min, but <10 min (≥ 10 min is a baseline change) |
| | Recurrent | Occur with $\geq 50\%$ of uterine contractions in any 20-min window |
| | Intermittent | Occur with $<50\%$ of uterine contractions in any 20-min window |
| Contractions | Considerations | Frequency, duration, intensity, and relaxation |
| | Normal | ≤ 5 contractions per 10 min averaged over a 30-min window |
| | Tachysystole | >5 contractions per 10 min averaged over a 30-min window; should always be qualified as to the presence or absence of associated FHR decelerations |

FHR, Fetal heart rate.

contraction pattern (e.g., five contractions within 10 minutes or contractions lasting longer than 90 seconds) is also considered equivocal and requires further testing.

Ultrasound

Although routine sonography for low-risk pregnant women is controversial, few would disagree that the benefits far outweigh the costs for high-risk patients. Given the higher risk for fetal complications such as anatomic anomalies or growth disturbances, a specialized examination is performed between 18 and 20 weeks' gestation in most high-risk pregnancies.

Additional ultrasound modalities are also available, including fetal echocardiography, three-dimensional (3D) sonography, and Doppler. Cardiac anomalies are the most common major congenital defects encountered in the antepartum period. A four-chamber view of the heart at the time of fetal anatomy survey at 18 to 20 weeks' gestation will detect only 30% of congenital cardiac anomalies, although the detection rate can be increased to approximately 65%–90% if the outflow tracts are adequately visualized (Kirk et al., 1994; Li et al., 2013), but this still leaves 10%–35% of all congenital cardiac anomalies undiagnosed. Factors that affect the sensitivity include type of practice (university-based vs community-based), operator training and experience, GA at the time of scan, maternal weight, fetal position, and type of defect present (Tegnander and Eik-Nes, 2006). For this reason, fetal echocardiography should be performed by a skilled and experienced sonologist at 20 to 22 weeks' gestation in all pregnancies at high-risk of a fetal cardiac anomaly; this includes pregnancies complicated by pregestational diabetes mellitus, a personal or family history of congenital cardiac disease (regardless of the nature of the lesion or whether it has been repaired), maternal drug exposure (e.g., lithium and valproic acid) (Bérard et al., 2007), and pregnancies conceived by in vitro fertilization, but not if the pregnancy was conceived using clomiphene citrate or ovarian stimulation or intrauterine insemination alone (Olson et al., 2005).

Compared with standard two-dimensional (2D) ultrasound, 3D ultrasound (or four-dimensional [4D] if fetal movements are included) allows for visualization of fetal structures in all three dimensions concurrently for the improved characterization of complex fetal structural anomalies and for storage of scanned images with 3D reconstruction at a later date or remote location (telemedicine). Unlike 2D ultrasound, 3D images are greatly influenced by fetal movements and are subject to more interference from structures such as fetal limbs, umbilical cord, and placental tissue. Because of movement interference, visualization of the fetal heart with 3D ultrasound is suboptimal.

In addition to rapid acquisition of images that can be later reconstructed and manipulated, 3D ultrasound has other potential advantages:

- Surface rendering mode can provide clearer images of many soft tissue structures. Such images can improve the diagnosis of certain fetal malformations, especially craniofacial anomalies (cleft lip and palate, micrognathia, ear anomaly, facial dysmorphism, club foot, finger and toe anomalies), intracranial lesions, spinal anomalies, ventral wall defects, and fetal tumors.
- 3D ultrasound may be useful in early pregnancy by providing more accurate measurements of the gestational sac, yolk sac, and crown-rump length. It may also allow for a more accurate midsagittal view of the fetus for measuring nuchal translucency.
- 3D ultrasound can also be used to measure tissue volume. Preliminary data suggest that the assessment of cervical volume

• **Fig. 14.3** A Contraction Stress Test. The fetal heart rate is plotted above the uterine contraction signal. Note the late deceleration after a contraction; this is a positive, or abnormal, test result. *FHR*, Fetal heart rate; *NST*, nonstress test.

may predict the risk of cervical insufficiency (Rovas et al., 2005), and measurement of placental volume in the first trimester may predict fetuses at risk of FGR (Schuchter et al., 2001).

Despite these advantages and the fact that 3D ultrasound has been available since the early 1990s, it has yet to live up to its promises. Although 3D ultrasound is unlikely to replace standard 2D imaging in the near future, it is a valuable complementary modality in obstetric imaging. As the technology improves, it is likely that perinatal ultrasound will evolve to resemble computed tomography (CT) and MRI.

Growth Assessment

Normal fetal growth is a critical component of a healthy pregnancy and the subsequent long-term health of the child. A systematic method of physical examination of the gravid abdomen was first described by Leopold and Spörlin (1894). Although this examination has several limitations, particularly in the setting of maternal obesity, multiple pregnancy, uterine fibroids, or polyhydramnios, it is safe, low cost, and well tolerated and may add valuable information to assist in antepartum management. Palpation is divided into four separate Leopold maneuvers. Each maneuver is designed to identify specific fetal landmarks or to reveal a specific relationship between the fetus and mother. For example, the first maneuver involves measuring fundal height. The uterus can be palpated above the pelvic brim at approximately 12 weeks' gestation. Thereafter, fundal height should increase by approximately 1 cm per week, reaching the level of the umbilicus at 20 to 22 weeks' gestation. Between 20 and 32 weeks' gestation, the fundal height (in centimeters, from the superior edge of the pubic symphysis) is approximately equal to the GA (in weeks) in healthy women of average weight with an appropriately grown fetus. However, there is a wide range of normal fundal height measurements. One study has shown a 6-cm difference between the 10th and 90th percentiles at each week of gestation after 20 weeks (Belizan et al., 1978). Moreover, fundal height is maximal at approximately 36 weeks' gestation, at which time the fetus drops into the pelvis in preparation for labor and the fundal height decreases. For these reasons, reliance on fundal height measurements alone will fail to identify more than 50% of fetuses with FGR (Gardosi and Francis, 1999). Serial fundal height measurements by an experienced obstetric care provider are more accurate than a single measurement and will lead to an improved diagnosis of FGR, with reported sensitivities as high as 86% (Belizan et al., 1978). However, a more recent

systematic review failed to conclude that serial fundal height measurements were superior to abdominal palpation alone due to a lack of randomized controlled trials (Robert et al., 2015).

If the clinical examination is not consistent with the stated GA, an ultrasound examination is indicated to confirm GA and to establish a more objective measure of fetal growth. Ultrasound examination may also identify an alternative explanation for the discrepancy, such as multiple pregnancy, polyhydramnios, oligohydramnios, fetal demise, or uterine fibroids.

For many years, obstetric sonography has used fetal biometry to define fetal size by weight estimation, although this approach has a number of key limitations. For example, regression equations used to create weight estimation formulas are derived primarily from cross-sectional data that rely on infants delivering within an arbitrary period of time after the ultrasound examination, and they assume that body proportions (i.e., fat, muscle, bone) are the same for all fetuses. Moreover, growth curves for healthy infants from 24 to 37 weeks' gestation rely on data collected from pregnancies delivered preterm, which should not be regarded as normal pregnancies and are likely to be complicated by some element of uteroplacental insufficiency, regardless of whether the delivery was spontaneous or iatrogenic. Despite these limitations, if the GA is well validated, the prevailing data suggest that prenatal ultrasound can be used to verify an alteration in fetal growth in 80% of cases and exclude abnormal growth in 90% of cases (Sabbagha, 1987).

Sonographic estimates of fetal weight are commonly derived from mathematical formulas that use a combination of fetal measurements, especially the BPD, AC, and femur length (Hadlock et al., 1984). Whereas the BPD may be the most accurate indicator of GA in the second or third trimesters, fetuses gain weight in their abdomen, making the AC the single most important measurement for fetal size. The AC is thus given more weight in these formulas. Unfortunately, the AC is also the most difficult measurement to acquire, and a small difference in the AC measurement will result in a large difference in the estimated fetal weight (EFW). The accuracy of the EFW depends on a number of variables, including GA (in absolute terms, EFW is more accurate in preterm or FGR fetuses than in term or macrosomic fetuses), operator experience, maternal body habitus, and amniotic fluid volume (measurements are more difficult to acquire if the amniotic fluid volume is low). Although objective, sonographic EFW estimations are not particularly accurate and have an error of 15%–20%, even in experienced hands (Anderson et al., 2007). Indeed, a sonographic EFW at term is no more accurate than a clinical

estimate of fetal weight by an experienced obstetric care provider or the mother's estimate of fetal weight if she has delivered before (Chauhan et al., 1992). Sonographic estimates of fetal weight must therefore be evaluated within the context of the clinical situation and balanced against the clinical estimate of fetal weight. Serial sonographic evaluations of fetal weight are more useful than a single measurement in diagnosing abnormal fetal growth. The ideal interval to evaluate fetal growth is every 3 to 4 weeks, with a minimum 10-day to 14-day interval necessary to see significant differences. Because of the inherent error in fetal biometric measurements, more frequent ultrasound determinations of EFW may be misleading. Similarly, the use of population-specific growth curves, if available, will improve the ability of the obstetric care provider to identify abnormal fetal growth. For example, growth curves derived from a population that lives at high altitude, where the fetus is exposed to lower oxygen tension, will be different from those derived from a population at sea level. Abnormal fetal growth can be classified as insufficient (i.e., FGR) or excessive (fetal macrosomia).

The definition of FGR has been a long-standing challenge for modern obstetrics. Distinguishing the healthy, constitutionally small fetus, defined as an EFW below the 10th percentile for a given week of gestation, from the nutritionally deprived, truly growth-restricted fetus has been particularly difficult. Fetuses with an EFW less than the 10th percentile are not necessarily pathologically growth restricted. Conversely, an EFW greater than the 10th percentile does not mean that an individual fetus has achieved its growth potential, and such fetuses may still be at risk of perinatal mortality and morbidity. As such, the most widely utilized definition of FGR is EFW less than the 10th percentile for GA in a well-dated pregnancy (ACOG, 2013; Copel and Bahtiyar, 2014). More restrictive definitions of FGR (EFW less than the 5th or 3rd percentiles) can identify fetuses at higher risk for pathologic growth restriction as opposed to constitutionally small fetuses. Additional findings suggestive of fetal compromise like oligohydramnios or abnormal umbilical artery Doppler velocimetry increase the likelihood of pathologic fetal growth restriction.

FGR can be classified into maternal, fetal, or placental etiologies (see Table 14.1). These distinct pathophysiologic mechanisms associated with FGR may occur in isolation or collectively but result in the common final pathway of suboptimal fetal growth and compromised fetal nutrition. Fetuses affected by poor antepartum growth may be further categorized as having symmetric or asymmetric FGR. In cases of symmetric FGR, both the fetal head size and body weight are reduced, indicating a global insult that probably occurred early in gestation. Symmetric FGR may reflect an inherent fetal abnormality (e.g., fetal chromosomal abnormality, inherited metabolic disorder, early congenital infection) or long-standing severe placental insufficiency caused by an underlying maternal disease (e.g., maternal hypertension, long-standing pregestational diabetes, or a significant collagen vascular disorder). Asymmetric FGR is characterized by suboptimal body growth with preserved head growth. It is more commonly observed in the third trimester and is thought to result from a later pathologic event, such as chronic placental abruption leading to uteroplacental insufficiency, in an otherwise uncomplicated pregnancy and healthy fetus.

Currently, patients with risk factors for FGR, those who develop obstetric complications, and those identified with lagging symphysial fundal height measurements are subsequently screened with ultrasound to assess fetal growth. This screening algorithm is in place in the United States, the UK, and various other countries; however, it is known to be imprecise and many fetuses at risk for

growth restriction as well as perinatal mortality are not identified with this system. For this reason, a prospective cohort study evaluated screening for FGR with a universal third-trimester ultrasound to assess fetal growth (Sovio et al., 2015). The authors found that standard screening for FGR identified 20% of small for gestational age (SGA) infants, and implementation of universal screening identified 57% of SGA infants. The increased sensitivity resulted in a decrease in specificity from 98% to 90%, resulting in an increased number of false-positive cases. Therefore implementation of a universal screening program to identify fetuses at risk for growth restriction and increased perinatal mortality would have to take into consideration the issue of over-identification of possible at-risk fetuses and subsequent overtreatment.

Early and accurate diagnosis of FGR coupled with appropriate intervention will lead to an improvement in perinatal outcome. If FGR is suggested clinically and by ultrasound examination, thorough evaluations of the mother and fetus are indicated. Referral to a maternal–fetal medicine specialist should be considered. Every effort should be made to identify the cause of FGR and to modify or eliminate contributing factors. Up to 20% of cases of severe FGR are associated with fetal chromosome abnormalities or congenital malformations, 25%–30% are related to maternal conditions characterized by vascular disease, and a smaller proportion are the result of abnormal placentation. However, in a substantial number of cases (50% or more in some studies), the cause of the FGR will remain uncertain even after a thorough investigation (Resnik, 2002).

Fetal macrosomia is defined as an EFW (not birthweight) of 4500 g or greater, measured either clinically or by ultrasound, and is independent of GA, diabetic status, or actual birthweight (ACOG, 2000). Fetal macrosomia refers to a single cutoff EFW; this should be distinguished from the large for GA fetus, which is one in whom the EFW is greater than the 90th percentile for GA. By definition, 10% of all fetuses are large for GA at any given GA. Fetal macrosomia is associated with an increased risk of cesarean delivery, operative vaginal delivery, and birth injury to both the mother (including vaginal, perineal, and rectal trauma) and the fetus (orthopedic and neurologic injury) (O'Sullivan et al., 1973; Widness et al., 1985; Magee et al., 1993; Kjos and Buchanan, 1999; ACOG, 2000). Shoulder dystocia with resultant brachial plexus injury (Erb palsy) is a serious consequence of fetal macrosomia and is further increased in the setting of diabetes because of the increased diameter of the upper thorax and neck of those fetuses.

Fetal macrosomia can be determined clinically, by abdominal palpation using Leopold maneuvers, or by ultrasound examination; these two techniques appear to be equally accurate (Watson et al., 1988). However, EFW measurements are less accurate in large (macrosomic) fetuses than in normally grown fetuses, and factors such as low amniotic fluid volume, advancing GA, maternal obesity, and the position of the fetus can compound these inaccuracies. Clinical examination has been shown to underestimate the birthweight by 0.5 kg or more in almost 80% of fetuses with macrosomia (Niswander et al., 1970). For these reasons, the prediction of fetal macrosomia is not particularly accurate, with a false-positive rate of 35% and a false-negative rate of 10% (Niswander et al., 1970; Watson et al., 1988). A number of alternative sonographic measurements have therefore been proposed in an attempt to better identify the macrosomic fetus, including fetal AC alone, umbilical cord circumference, cheek-to-cheek diameter, and upper arm circumference; however, these measurements remain investigational and should not be used clinically.

Despite the inaccuracy in the prediction of fetal macrosomia, an EFW should be documented either by clinical estimation or ultrasound examination in all women at high risk for fetal macrosomia at approximately 38 weeks' gestation. Suspected fetal macrosomia is not an indication for induction of labor, because induction does not improve maternal or fetal outcomes (ACOG, 2000). However, if the EFW is excessive, an elective cesarean delivery should be considered to prevent fetal and maternal birth trauma. Although controversy remains as to the precise EFW at which an elective cesarean delivery should be recommended, a suspected birthweight in excess of 4500 g in women with diabetes or 5000 g in women without diabetes is a reasonable threshold (ACOG, 2000, 2001, 2002).

Amniotic Fluid Assessment

Amniotic fluid plays a key role in the health and development of a growing fetus. Once considered an afterthought during the ultrasound examination of the fetus, evaluation of the amniotic fluid is now considered an integral part of ultrasound evaluation for fetal well-being. Amniotic fluid serves a number of important functions for the developing embryo and fetus. It provides cushioning against physical trauma; creates an environment free of restriction and or distortion, allowing for normal growth and development of the fetus; provides a thermally stable environment; allows the respiratory, gastrointestinal, and musculoskeletal tracts to develop normally; and helps to prevent infection (Hill et al., 1984).

The chorioamnion acts as a porous membrane early in pregnancy, allowing the passage of water and solutes across the membrane; there is little contribution from the small embryo. As the pregnancy progresses into the late first trimester, the diffusion of fluid across the fetal skin occurs, increasing the volume of amniotic fluid. In the second half of the pregnancy, the main sources of amniotic fluid come from fetal kidneys and lungs. The primary sources for removal of fluid are from fetal swallowing and absorption into fetal blood perfusing the surface of the placenta. As more fluid is produced than is resorbed by the fetal-placental unit, the volume of amniotic fluid increases throughout the first 32 weeks of pregnancy (Fig. 14.4). The volume peaks at approximately 32 to

33 weeks' gestation, and at this GA, equal amounts of fluid are produced and resorbed. After term, the amniotic fluid declines at a rate of 8% per week (Brace and Wolf, 1989).

Because amniotic fluid plays a critical role in the normal development of a fetus, the assessment of amniotic volume is an essential component of the ultrasound evaluation for fetal well-being. Subjective estimates of the amniotic fluid volume have been validated, but two ultrasound measurements – amniotic fluid index (AFI) and maximum vertical pocket (MVP) – have been developed to quickly and accurately assess the quantity of amniotic fluid surrounding the fetus.

The AFI is a semiquantitative method for assessing the amniotic fluid volume with ultrasound. The gravid uterus is divided into four quadrants using the umbilicus, linea nigra, and external landmarks (Rutherford et al., 1987). The deepest amniotic fluid pocket is measured in each quadrant with the ultrasound transducer perpendicular to the floor. The four measurements are added together, and the sum is regarded as the AFI. Pockets filled with umbilical cord or fetal extremities should not be used for generating the AFI (Hill, 1997). Researchers and clinicians have used a variety of measurements to define abnormalities in amniotic fluid volume. However, the normal range of the AFI most commonly used in clinical practice is greater than 5 to less than 24 cm of fluid. Pregnancies with an AFI of greater than 5 are described as having oligohydramnios, and pregnancies with measurements greater than 24 cm are described as having polyhydramnios (Reddy et al., 2014).

The MVP is another semiquantitative method for assessing the fluid volume. The technique involves scanning the gravid uterus for the single deepest pocket of amniotic fluid that is free of umbilical cord and fetal parts and, with the transducer perpendicular to the floor, measuring the pocket of fluid (Manning et al., 1981b). Oligohydramnios is defined as a single measurement of less than 2 cm. Polyhydramnios is defined as a single measurement greater than 8 cm. In contrast to AFI, this method can be used for both singleton and multiple gestation pregnancies. Currently, MVP is preferred to AFI not only because of its ease to perform but also because the use of MVP compared with AFI results in fewer obstetric interventions without a significant difference in perinatal outcome (Nabhan and Abdelmoula, 2009).

Otherwise normal pregnancies affected by oligohydramnios are at increased risk for perinatal mortality as decreased amniotic fluid volume can be used as a proxy for declining uteroplacental perfusion and increasing placental dysfunction. Decisions to intervene in a pregnancy affected by oligohydramnios are based upon several factors such as GA, fetal condition, and maternal characteristics. First, rupture of membranes must be ruled out, as a low amniotic fluid volume in the setting of ruptured membranes is no longer predictive of poor placental perfusion. Expert opinion recommends delivery after 36 to 37 weeks' gestation in the setting of isolated and persistent oligohydramnios (MVP <2 cm) in an otherwise uncomplicated pregnancy (ACOG, 2014b).

Biophysical Profile

An NST alone might not be sufficient to confirm fetal well-being; in such cases, a BPP may be performed. The BPP refers to a sonographic scoring system performed over a 30-minute to 40-minute period designed to assess fetal well-being. The BPP was initially described for testing postterm fetuses but has since been validated for use in both term and preterm fetuses (Manning et al., 1981a, 1985, 1987; Vintzileos et al., 1983, 1987a, 1987b). Notably, BPP is not validated for use in active labor. The five variables

• **Fig. 14.4** Amniotic Fluid Index (in mm) Plotted Against Gestational Age. The curves represent percentiles. AFI, Amniotic fluid index.

described in the original BPP were gross fetal body movements, fetal tone (i.e., flexion and extension of limbs), amniotic fluid volume, fetal breathing movements, and NST (summarized in Table 14.2) (Manning, 1989). More recently, however, BPP is interpreted without the NST.

The individual variables of the BPP become apparent in healthy fetuses in a predictable sequence: fetal tone appears at 7.5 to 8.5 weeks, fetal movement at 9 weeks, fetal breathing at 20 to 22 weeks, and FHR reactivity at 24 to 28 weeks' gestation. Similarly, in the setting of antepartum hypoxia, these characteristics typically disappear in the reverse order in which they appeared (i.e., FHR reactivity is lost first, followed by fetal breathing, fetal movements, and finally fetal tone) (Vintzileos et al., 1987a). The amniotic fluid volume, which is composed almost entirely of fetal urine in the second and third trimesters, is not influenced by acute fetal hypoxia or acute fetal CNS dysfunction. Rather, oligohydramnios (decreased

amniotic fluid volume) in the latter half of pregnancy and in the absence of ruptured membranes is a reflection of chronic uteroplacental insufficiency, increased renal artery resistance leading to diminished urine output, or both (Oz et al., 2002); it predisposes to umbilical cord compression, thus leading to intermittent fetal hypoxemia, meconium passage, or meconium aspiration. Adverse pregnancy outcome (including abnormal FHR tracing, low Apgar score, and neonatal intensive care unit admission) is more common when oligohydramnios is present (Bochner et al., 1987; Tongsong and Srisomboon, 1993; Oz et al., 2002; Morris et al., 2003). Serial (weekly) screening of high-risk pregnancies for oligohydramnios is important, because amniotic fluid can become drastically reduced within 24 to 48 hours (Clement et al., 1987).

Although each of the five features of the BPP is scored equally (2 points if the variable is present or normal and 0 points if absent or abnormal, for a total of 10 points), they are not equally predictive of adverse pregnancy outcome. For example, amniotic fluid volume is the variable that correlates most strongly with adverse pregnancy events. The recommended management based on the BPP is summarized in Table 14.3 (Manning, 1989). A score of 8–10 out of 10 is regarded as reassuring; a score of 4–6 is suspicious and requires reevaluation, and a score of 0–2 suggests abnormal fetal testing – previously referred to as *fetal distress* (Manning et al., 1981a, 1981b). Evidence of abnormal fetal testing or oligohydramnios in the setting of otherwise normal fetal testing should prompt evaluation for immediate delivery (Vintzileos et al., 1987a, 1987b).

It is important to recognize that administration of maternal systemic steroids to promote fetal maturity may result in fetal behavioral changes. Subsequent to systemic steroid administration, fetal body movements may decrease, FHR variability may decrease, and fetal breathing episodes may be less frequent (Rotmensch et al., 2005; Verdurmen et al., 2013). These changes in fetal activity and FHR patterns are important to take into consideration when interpreting the various components of the fetal BPP.

TABLE 14.2 Fetal Biophysical Profile

| Element | Criterion (2 Points for Each Element Satisfied) |
|----------------|---|
| Breathing | ≥1 episode of breathing movements lasting 30 s |
| Movement | ≥3 discrete body or limb movements |
| Tone | ≥1 episode of active extension and flexion of limbs or trunk |
| Amniotic fluid | ≥1 pocket of amniotic fluid measuring ≥2 cm in two perpendicular planes |
| NST | ≥2 FHR accelerations lasting ≥15 s over 20 min |

FHR, Fetal heart rate; *NST*, nonstress test.

TABLE 14.3 Interpretation and Management of Biophysical Profile

| Score | Comment | Perinatal Morbidity or Mortality Within 1 Week (No Intervention) | Management |
|--------------------------------|--|--|---|
| 10/10 | Normal | <1/1000 | No intervention |
| 8/8 | Normal | — | No intervention |
| 8/10 (abnormal NST) | Normal | — | No intervention |
| 8/10 (abnormal amniotic fluid) | Suspect chronic fetal compromise, renal anomaly, or rupture of membranes | 89/1000 | Rule out renal abnormality or rupture of membranes; consider delivery or prolonged observation if dictated by gestational age |
| 6/8 (other) | Equivocal, possible asphyxia | Variable | If fetus is mature, deliver; if immature, repeat test within 4–6 hours |
| 6/8 (abnormal amniotic fluid) | Suspect asphyxia | 89/1000 | Repeat 4–6 hours; consider delivery |
| 4/8 | Suspect asphyxia | 91/1000 | If ≥36 weeks' gestation or documented pulmonary maturity, deliver immediately; if not, repeat within 4–6 hours |
| 2/8 | High suspicion of asphyxia | 125/1000 | Immediate delivery |
| 0/8 | High suspicion of asphyxia | 600/1000 | Immediate delivery |

Adapted from Manning FA, Morrison I, Harman CR, Lange IR, Menticoglou S. Fetal assessment based on fetal biophysical profile scoring: experience in 19,221 referred high-risk pregnancies. *Am J Obstet Gynecol.* 1987;157:880–884.

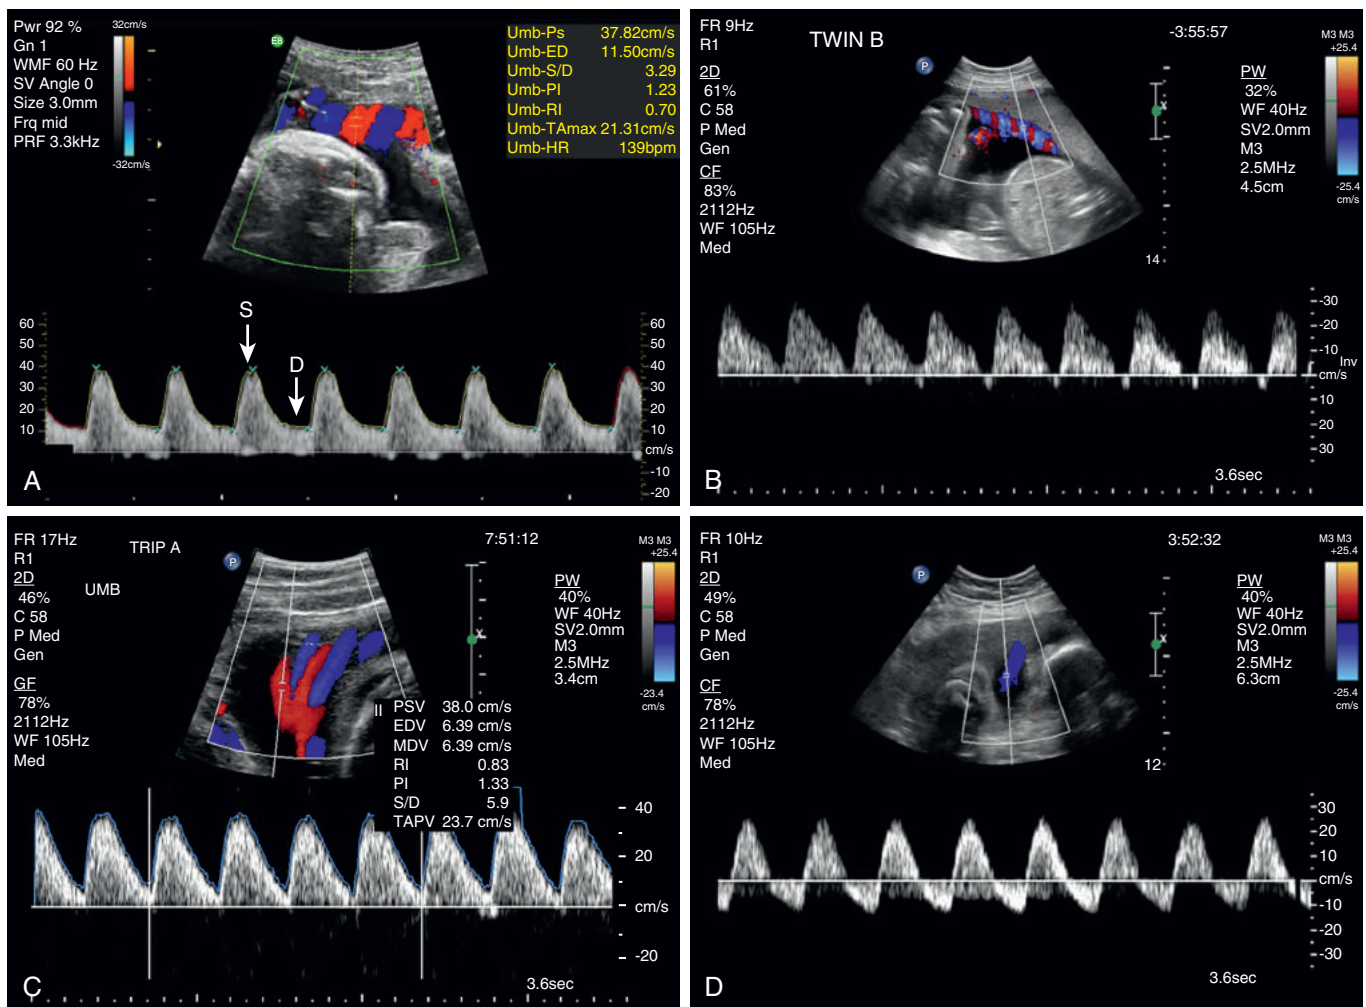

Doppler

Doppler velocimetry shows the direction and characteristics of blood flow, and it can be used to examine the maternal, utero-placental, or fetal circulations. Because of placental capacitance, the umbilical artery is one of the few arteries that normally has forward diastolic flow, and it is one of the most frequently targeted vessels during pregnancy (Fig. 14.5). Umbilical artery Doppler velocimetry measurements reflect resistance to blood flow from the fetus to the placenta. Factors that affect placental resistance include GA, placental location, pregnancy complications (placental abruption, preeclampsia), and underlying maternal disease (chronic hypertension).

Doppler velocimetry of umbilical artery blood flow provides an indirect measure of placental function and fetal status (Giles et al., 1985). Decreased diastolic flow with a resultant increase in systolic-to-diastolic ratio suggests increased placental vascular resistance and fetal compromise. Severely abnormal umbilical artery Doppler velocimetry (defined as absent or reversed diastolic flow) is an especially ominous observation and is associated with poor perinatal outcome, particularly in the setting of FGR (Fig. 14.6A–D)

• **Fig. 14.5** Normal Fetal Umbilical Artery Doppler Recording. EDV, End diastolic velocity; PSV, peak systolic velocity; S/D, systolic/diastolic ratio.

• **Fig. 14.6** Uterine Artery Doppler to Assess Growth Restriction. Increasing levels of placental resistance as seen in the umbilical artery at the time of diastole (D) as it relates to systole (S). Normal end-diastolic flow (A), decreased end diastolic flow (B), absent end-diastolic flow (C), and reversed end-diastolic flow (D). EDV, End diastolic velocity; PSV, peak systolic velocity; S/D, systolic/diastolic ratio.

(McCallum et al., 1978; Ducey et al., 1987; Rochelson et al., 1987; Trudinger et al., 1991; Wenstrom et al., 1991; Zelop et al., 1996). The overall mortality rate for fetuses with absent or reversed flow may be near 30% (Karsdorp et al., 1994). It should be noted that abnormal Doppler studies are often seen in cases of anatomic anomalies or chromosomal abnormalities, which should be noted when managing a case. A 2013 systematic review (Alfirevic et al., 2013) found evidence that use of umbilical artery Doppler ultrasound in high-risk pregnancies (FGR/suspected placental insufficiency) reduced the risk of perinatal deaths and resulted in less obstetric interventions.

The role of ductus venosus and middle cerebral artery (MCA) Doppler in the management of FGR pregnancies is not well defined. As such, urgent delivery should be considered in FGR pregnancies when the results of umbilical artery Doppler studies are severely abnormal, regardless of GA. However, it is unclear how to interpret these findings in the setting of a normally grown fetus. For these reasons, umbilical artery Doppler velocimetry should not be performed routinely on low-risk women. Appropriate indications include FGR, cord malformations, unexplained oligohydramnios, suspected or established preeclampsia, and possibly fetal cardiac anomalies. Umbilical artery Doppler velocimetry has not been shown to be useful in the evaluation of a variety of high-risk pregnancies, including diabetic and postterm pregnancies, primarily because of its high false-positive rate (Farmakides et al., 1988; Landon et al., 1989; Stokes et al., 1991; Baschat, 2004).

As such, in the absence of FGR, obstetric management decisions are not usually made on the basis of Doppler velocimetry studies alone. Nonetheless, new applications for Doppler technology are currently under investigation. An application that has proved extremely useful is the noninvasive evaluation of fetal anemia resulting from isoimmunization. When a fetus develops severe

• **Fig. 14.7** Middle Cerebral Artery Peak Systolic Velocity for Fetal Anemia Assessment. EDV, End diastolic velocity; PSV, peak systolic velocity; S/D, systolic/diastolic ratio.

anemia, cardiac output increases and there is a decline in blood viscosity, resulting in an increase in MCA blood flow, which can be demonstrated by measuring the peak velocity using MCA Doppler velocimetry (Fig. 14.7) (Mari et al., 1995). This demonstration can help the perinatologist to better counsel such patients about the need for cordocentesis and fetal blood transfusion. Doppler studies of other vessels – including the uterine artery, fetal aorta, ductus venosus, and fetal carotid arteries – have contributed considerably to our knowledge of maternal–fetal physiology but as yet have resulted in few clinical applications.

Summary

There are a variety of testing modalities available to the obstetrician for assessing fetal well-being in the antepartum period, each with specific applications, advantages, and disadvantages. As such, it is difficult to apply generalized protocols to the assessment of the fetus. A stepwise approach entails applying the appropriate tests for low-risk patients and identifying those patients, from the results of

those tests or from historical factors, for whom further testing is needed. Although many tests, including NST, fetal weight assessment, and uterine artery Doppler, may be somewhat nonspecific and may have misleading false-positive rates, combining those tests with others increases the specificity. Test results that raise concerns require further investigation or active management.

Complicated Deliveries

KARA K. HOPPE AND THOMAS J. BENEDETTI

KEY POINTS

- Cesarean section occurs in approximately one-third of all births, with substantial variation among hospitals that cannot be entirely accounted for by preexisting maternal or fetal comorbidities.
- Multidisciplinary team training can reduce infant morbidity after shoulder dystocia.
- Operative vaginal birth with either forceps or vacuum has declined to a multi-decade low despite the low frequency of infant complications directly attributable to this method of delivery.
- Regardless of mode of delivery, both the obstetrician and pediatrician must be aware that the infant in breech presentation requires careful attention upon birth for the presence of hip dislocation and traumatic morbidity (soft tissue trauma, fracture, facial nerve paralysis, and brachial plexus palsy).
- Twin gestations have increased and now account for 3% of total births, 17% of preterm births, and approximately 25% of infants of low birth weight and very low birth weight.
- Vaginal birth after cesarean (VBAC) section should occur in delivery facilities capable of rapidly performing an emergent cesarean section, because this improves the likelihood of minimizing adverse neonatal sequelae.

Overview

Historically, childbirth was often regarded as a perilous undertaking. However, over the past century in the United States, perinatal and maternal mortality have dramatically fallen with advances in modern obstetric care, such as widespread use of antibiotics, easy access to expedient cesarean delivery, and better understanding of the proper use of instruments such as forceps and vacuum extraction (Ali and Norwitz, 2009). Indeed, adverse outcomes are generally uncommon in modern obstetrics and, unlike in the past, most labor and delivery concludes with a healthy mother and neonate. Nevertheless, complicated deliveries still exist, and knowledge of their conduct and sequelae is still required for the administration of proper maternal and infant care.

In this chapter we will first address the complicated vaginal delivery, with particular attention to neonatal outcomes. We will then discuss cesarean delivery and vaginal birth after cesarean (VBAC) delivery and what neonatal implications these may have. Before discussing complicated labor and its neonatal effects, it is

important to have a brief understanding of the conduct of normal labor and delivery. A comprehensive discussion of labor and delivery is beyond the scope of this chapter, and the interested reader is directed to *Williams Obstetrics*, 24th ed, Chapter 2 on normal labor (Cunningham et al., 2014).

Vaginal Delivery

The first stage of labor begins with the onset of regular uterine contractions with concomitant cervical dilation and effacement, and it ends with complete cervical dilation. The first stage is traditionally (Friedman, 1954) further subdivided into a latent phase, the length of which is variable and can last for several hours, and an active phase, which usually begins when the cervix is dilated 4 cm and is marked by further rapid, progressive cervical dilation and effacement. Often the diagnosis of the transition from latent to active phase labor is retrospective, because the time of onset of active labor is variable by patient. The second stage begins with complete cervical dilation and terminates with the expulsion of the fetus from the birth canal. The third stage of labor concludes with the delivery of the placenta.

Disorders of the conduct of labor are of either protraction, in which cervical dilation or fetal descent occurs but is at a rate much less than expected, or arrests. Both disorders are addressed by operative delivery if they are unresponsive to active medical management; this can be performed abdominally through cesarean section or vaginally by obstetric forceps or vacuum extraction if the cervix is fully dilated and specific criteria are fulfilled (see later discussion on [operative vaginal delivery](#)). All these modalities can have neonatal and maternal adverse effects, and the choice of instrument or mode of delivery must always be selected taking these potential morbidities into account.

In 2010, data from the Consortium on Safe Labor stimulated debate regarding whether the 60-year-old data of Friedman apply to currently laboring women (Zhang et al., 2010). In this retrospective study conducted at US hospitals, the duration of labor was analyzed in over 60,000 women, each of whom vaginally delivered a singleton vertex fetus and had a normal perinatal outcome. The 95th percentile rate of active phase dilation was found to be slower than the standard rate derived from Friedman's work. Two important differences were found.

First, from 4 to 6 cm, both nulliparous and multiparous women dilated more slowly than historically described. After 6 cm,

multiparous women dilated more rapidly than primiparous women. Secondly, the active phase often did not start until at least 6 cm. Although challenged by Friedman and Cohen, many obstetricians feel that the Consortium on Safe Labor data, rather than the standards proposed by Friedman, should inform evidence-based labor management (Cohen and Friedman, 2015). In 2012 a summary was published by a joint committee including the Eunice Kennedy Shriver National Institute of Child Health and Human Development, Society for Maternal-Fetal Medicine, and American College of Obstetricians and Gynecologists (ACOG) Workshop (Spong et al., 2012) regarding labor management guidelines largely based on the work of Zhang. Further studies will be necessary to determine whether the newer data from Zhang will supersede the work of Friedman.

Cesarean Section

A cause-and-effect relationship between cesarean delivery and improved neonatal outcomes in the United States has never been demonstrated. Currently, almost one mother in three is giving birth by cesarean section, a record level for the United States. The rate of cesarean delivery in the United States, which peaked in 2009 at 32.9%, had declined only slightly to 32.4% by 2014 (Hamilton et al., 2015). Recommendations from the US Department of Health and Human Services Healthy People 2010 recommend a cesarean section rate of less than 15% for a first pregnancy and 63% for previous cesarean sections. However, recent international data have called into question the safety of this low projection. In this extensive international study of World Health Organization (WHO) member countries, they found that a cesarean section rate up to 19% was associated with lower maternal and neonatal mortality than cesarean section rates lower than 19% (Molina et al., 2015).

There are, however, wide variations in cesarean delivery rates among individual states in the United States (Hamilton et al., 2015) and among individual hospitals within a given state (Main et al., 2012). This cesarean section variability was shown to be 10-fold (7%–70%) among birthing hospitals in the United States and varied from 17.5%–31.8% among the 50 states. This suggests that factors other than pregnancy risk indicators may heavily influence the current cesarean delivery rate. Liability fears have been suggested as a leading cause of the variability in cesarean section rates. One study has lent validity to this concern, showing that higher cesarean section rates were associated with reduced risk of litigation (Jena et al., 2015). This rise in cesarean delivery has been associated with a parallel drop in the vaginal operative delivery rate to less than 5%.

These two parallel trends have increased the cost of childbirth in the United States and are now presenting challenges to many state budgets, as nearly 50% of obstetric care cost is paid for with public funds (i.e., Medicaid). In response to a looming budget crisis, the state of Washington reduced hospital payment for uncomplicated cesarean delivery (DRG 371: Cesarean section) by reimbursing only the equivalent of a complicated vaginal birth (DRG 372: Normal delivery with problems), a projected savings of \$2 million per year. Many states are actively working to reduce the rate of cesarean delivery. Projects are under way to reduce elective delivery before 39 weeks' gestation, safely promote VBAC, and reduce the hospital and individual practitioner's variability in cesarean section rates. Whether this can be accomplished on a large scale without adversely affecting maternal and child health remains to be seen.

Cesarean section is usually performed through either a Pfannenstiel or vertical skin incision. The uterine incision is often made transversely in the lower uterine segment, because it minimizes intraoperative blood loss and future risk of rupture during subsequent labor, compared with a vertical or classical incision. The risk of rupture in future labor is thought to be 0.5%–1.0% for a low transverse incision (ACOG, 2010). However, risks of uterine rupture with previous classical incision have ranged from 1%–12% in women undergoing a trial of labor (Halperin et al., 1988; Rosen et al., 1991; Landon et al., 2004). The ACOG Practice Bulletin, Number 115 quotes a 4%–9% risk of uterine rupture with a vertical or T-shaped uterine incision (ACOG, 2010).

Cesarean delivery is also performed for disorders of protraction or arrest in the first stage of labor when conservative measures, such as oxytocin or amniotomy, fail to augment delivery or in the second stage when assisted or operative vaginal delivery is deemed unfeasible or unsafe.

A partial list of other accepted indications for cesarean delivery is as follows:

1. Fetal malpresentation (e.g., shoulder or breech)
2. Placenta previa
3. Prior classical uterine incision
4. Fetal status not reassuring, remote from vaginal delivery
5. Higher-order multiple gestation (triplet or greater)
6. Fetal contraindications to labor (alloimmune thrombocytopenia)
7. Maternal contraindication to labor (e.g., history of rectal or perineal fistulas from inflammatory bowel disease, large lower-uterine segment, or cervical leiomyoma preventing vaginal delivery)
8. Maternal choice after counseling regarding risks versus benefits

Operative Vaginal Delivery: Obstetric Forceps and Vacuum Extraction

Description of the Obstetric Forceps

Obstetric forceps have been used to facilitate vaginal deliveries since 1500 BC. Most commonly, the invention is credited to Peter Chamberlen and his brother, both obstetricians from England. Designed originally as a means of extracting fetuses from women who were at high risk of dying during childbirth, forceps now are an alternative to cesarean delivery in women with a protracted second stage of labor. Originally, many of these instruments were furnished with hooks and other accessories of destruction, and they were intended to save the mother but not the fetus. Over the last 500 years, the modern instruments in current use have been through hundreds of modifications, safer techniques have been established, and the overriding goal now includes delivering an intact, living baby and a healthy mother (Meniru, 1996; O'Grady et al., 2002).

Current obstetric forceps were first devised for practical use in the 16th and 17th centuries and were perfected over the past 300 years into the models in current use. Although there are many variations on the standard blueprint, depending on the indication for its use, all obstetric forceps have a similar design.

Forceps are made of stainless steel and consist of two blades (each approximately 37.5 cm long, crossing each other), a lock at the site of crossing, and a handle, whereby the instrument is grasped by the obstetrician. The part of the forceps that grasps the fetal head is the blade; this is further divided into the heel, which is the part closest to the lock, and the toe, which is the most distal

• **Fig. 15.1** Simpson forceps: a standard obstetric forceps with features common to all such instruments.

TABLE 15.1 Types of Obstetric Forceps in Most Common Use

| Type | Anatomic Modification | General Use |
|-------------------|---|--|
| Classic | | |
| Tucker–McClane | Solid blade | Nonmolded vertex |
| Simpson | Parallel shanks | Molded vertex or significant caput |
| Elliot | Convergent shanks | Nonmolded vertex |
| Laufe | Pseudofenestrated blade; divergent shanks | For preterm infants or EFW <2500 g |
| Rotational | | |
| Kielland | English lock; absent pelvic curve | For rotation of fetal vertex $\geq 45^\circ$ |
| Breech | | |
| Piper | Long handles with no pelvic curvature | For after-coming head in breech vaginal delivery |

EFW, Estimated fetal weight.

part of the blade. The blade can be either fenestrated – meaning the body of the blade is hollow – or solid to prevent fetal head compression. A further modification is pseudofenestration, in which a solid blade has a ridged edge, combining the advantages of easier applicability and less fetal trauma that a solid blade affords with the ease of traction of a fenestrated blade. Obstetric forceps also possess a rounded cephalic curve, which accommodates the fetal vertex, and a pelvic curve that mirrors the maternal pelvic curve (Fig. 15.1).

There are more than 60 different types of obstetric forceps described in the literature, but most of them are not used currently. The forceps used most commonly today are described in Table 15.1, along with their indications for use and the variations in anatomy, which distinguish one from the other.

Indications for Use of Obstetric Forceps

To an individual without obstetric training, the use of forceps can appear to be a dangerous and difficult undertaking, fraught with potential trauma for both the mother and fetus. It is true that the use of this instrument, if not performed carefully or appropriately, can have serious consequences. Nevertheless, with properly trained hands, and a proper appreciation of its use, forceps have traditionally been lifesaving for both mother and fetus.

The criteria for the safe application of obstetric forceps are as follows:

1. The cervix must be fully dilated.
2. The position of the fetal vertex must be known. Forceps should not be applied when the fetal presentation is in doubt.
3. The fetal vertex must be engaged within the maternal pelvis. Often in difficult or challenging labors, significant caput can lead to the false impression that fetal station is lower than in reality. For this reason, the obstetrician must be confident that the actual biparietal diameter has passed the pelvic inlet (engagement) as evidenced by the leading part of the fetal skull beyond the level of the ischial spines. In addition, when the presentation is occiput posterior, the leading point of the fetal skull may appear to be lower in the pelvis, although the biparietal diameter has not yet passed through the pelvic inlet, and can lead to an erroneous conclusion about fetal station.
4. When the forceps are properly applied, the sagittal suture must be exactly midway between the blades, and the lambdoidal sutures should be equidistant from the edge of the blade.
5. If these conditions are not met, the delivery with forceps should be reconsidered.

The ACOG has revised its 1988 classification of the type of forceps delivery, according to the station of the fetal vertex before forceps application (ACOG, 2015), which is as follows:

1. Outlet forceps – the fetal vertex is visible at the labia without manually separating them, and the fetal skull has reached the pelvic floor.
2. Low forceps – the leading point of the fetal skull is >2 cm beyond the ischial spines.
3. Mid forceps – the fetal head is engaged (0 to +1 station). The forceps should be applied only if cesarean delivery is not quickly or imminently possible with the fetus in distress, or there should be a high likelihood that the forceps operation will be successful.
4. High forceps – the vertex is not engaged (leading part not at the level of the ischial spines or beyond). Under these circumstances, the forceps must never be applied.

The usual indications for use of the obstetric forceps are:

1. Maternal exhaustion or inability to push (endotracheal intubation with sedation or paralysis; neuromuscular disease)
2. Fetal heart tracing not reassuring
3. Maternal contraindications to pushing (cardiopulmonary disease, cerebrovascular aneurysm)
4. After-coming head in a vaginal breech delivery

Forceps and Potential Neonatal Morbidity

As stated previously, forceps were used for hundreds of years without regard to fetal survival and were primarily needed to facilitate or terminate difficult labors for maternal benefit. Today, with the widespread availability of cesarean delivery, considerations turn to providing the best neonatal outcome possible; therefore the difficult forceps deliveries of the past have largely been abandoned. Nevertheless, forceps can still play a role in modern obstetrics if judiciously used and in some circumstances can provide a safer alternative to cesarean delivery for both mother and baby.

The difficulty in interpreting the obstetric literature, in regard to neonatal morbidity incurred by forceps, is that the classification for type of forceps was revised by the ACOG in 1988; therefore prior studies do not use the same clinical criteria used currently to select appropriate candidates for forceps use. Furthermore, residency training in operative vaginal delivery has dramatically decreased over the past 30 years, potentially increasing fetal risk. Consequently, for modern interpretation of adverse outcomes, one

must look to studies performed after the 1988 ACOG revision of the classifications.

The incidence of operative vaginal delivery in the United States has declined to 3.2% of births, ranging by hospital from 1% to 23% (Hamilton et al., 2015). Forceps deliveries have declined to 0.5%, while vacuum deliveries account for the majority of operative births. The reported failure rate for forceps delivery is approximately <5% (Murphy and Koh, 2007). In general the failure rate increases as the station from which delivery is attempted decreases. The indication for forceps use varies widely by clinical situation, and the neonatal morbidity that can result from a “difficult pull” in a patient with a transverse arrest with marked fetal asynclitism may be different from the quick delivery of a 2600 g fetus whose mother is unable to push, even if both deliveries are by low forceps. Asynclitism refers to the position of a baby in the uterus such that the head of the fetus is presenting first and is tilted to the shoulder, causing the fetal head to no longer be in line with the birth canal.

There are few randomized prospective trials specifically addressing the issue of neonatal morbidity arising from forceps operations, and many of those are over 20 years old. In addition, there appears to be a substantial difference regarding frequency of operative delivery and outcomes between the United States and other English-speaking countries (UK and Australia) (Murphy and Koh, 2007). Again, the liability atmosphere in the United States is most likely to account for this difference in operative vaginal birth frequency and experience.

The primary outcome that birth attendants wish to avoid when considering operative vaginal birth is birth trauma to the baby primarily and secondarily to the mother. A large population-based study in the United States describing over 11 million births showed that birth trauma (facial nerve injury, cephalhematoma, intracranial hemorrhage, need for mechanical ventilation) was more likely with operative vaginal birth than spontaneous birth and even higher if sequential (vacuum and forceps) operative attempts had been made (Demissie et al., 2004). Vacuum-assisted births were associated with lower rate of birth injury, seizures, and assisted ventilation than forceps-assisted births. A large population-based study in California, however, found no differences in outcome with forceps versus vacuum except for a higher incidence of facial nerve palsy with forceps delivery (Towner and Ciotti, 2007). The absolute frequencies of birth trauma in these two large series were very similar and, although the rate of birth trauma was higher than spontaneous vaginal birth, the overall frequencies were actually quite low. For example, when comparing forceps versus spontaneous vaginal delivery the rates of intracranial hemorrhage were 1.5/1000 versus 0.4/1000, mechanical ventilation was 4/1000 versus 2/1000, and facial nerve palsy was 4/1000 versus 0.2/1000. Table 15.2 shows the incidence of intracranial injury by delivery mode.

The hazard of making such comparisons is that in most instances the decision facing the birth attendant is not operative delivery versus spontaneous birth but operative birth versus cesarean delivery. In this regard the data from Towner provided some important information. When comparing fetal outcomes after successful operative vaginal birth, unsuccessful operative vaginal birth, and cesarean section done for labor disorder without attempt at operative vaginal birth, the latter two were similar. The primary finding of this study was that there appeared to be an irreducible number of fetal injuries associated with labor rather than the method of delivery.

The clinical dilemma that has probably changed the frequency of operative delivery in the United States also comes from data presented by Towner and Ciotti (2007) as well as others (Gardella

TABLE 15.2 Risk of Neonatal Intracranial Hemorrhage^a According to Type of Delivery

| Mode of Delivery | Incidence of Intracranial Injury |
|------------------------------|----------------------------------|
| Vacuum | 1 in 860 |
| Forceps | 1 in 664 |
| Combined vacuum and forceps | 1 in 256 |
| Cesarean, in labor | 1 in 907 |
| Cesarean, not in labor | 1 in 2750 |
| Spontaneous vaginal delivery | 1 in 1900 |

^aIntracranial hemorrhage was defined as subdural, cerebral, intraventricular, or subarachnoid.

Adapted from Towner D, Castro MA, Eby-Wilkens E, Gilbert WM. Effect of mode of delivery in nulliparous women on intracranial injury. *N Engl J Med*. 1999;341:1709–1714.

et al., 2001; Fong et al., 2014). The dilemma is what to do in the instances in which operative vaginal birth fails. Towner showed that fetal injury was higher in sequential vaginal birth, even if successful, than with successful single operative attempts. Gardella et al. (2001) found the same thing and expended the excess morbidity to the mother as well. However, Towner found that the excess morbidity to the baby after failed vaginal birth was not reduced by cesarean section. Another study looking at outcomes of failed operative delivery also found worse neonatal outcomes, but these were nearly all in infants who had fetal heart rate abnormalities listed as either the primary or secondary reason for operative delivery (Alexander et al., 2009). The knowledge of morbidity associated with failed vaginal births by most obstetricians in the United States has appeared to have changed behavior regarding forceps attempts. In the second stage of labor if efforts to achieve spontaneous vaginal birth are unsuccessful, cesarean delivery is increasingly offered rather than attempted vaginal birth with the risk of failure and increased fetal morbidity. In many hospitals in the United States, the percentage of labor-related cesarean sections done in the second stage of labor exceeds 40%.

Vacuum Delivery: Indications, Uses, and Comparison With Forceps Procedures

Operative vaginal delivery for the indications listed previously can also be performed by the vacuum extractor. Vacuum extraction was first described in 1705 by Dr. James Yonge, an English surgeon, several decades before the invention of the obstetric forceps. However, it did not gain widespread use until the 1950s, when it was popularized in a series of studies by the Swedish obstetrician Dr. Tage Malmström. By the 1970s, the vacuum extractor had almost completely replaced forceps for assisted vaginal deliveries in most northern European countries, but its popularity in many English-speaking countries, including the United States and the UK, was limited. By 1992, however, the number of vacuum-assisted deliveries surpassed the number of forceps-assisted deliveries in the United States, and by the year 2000 approximately 66% of operative vaginal deliveries were by vacuum (Hillier and Johanson, 1994; Ali and Norwitz, 2009). This trend has continued to 2014, with approximately 85% of operative vaginal attempts performed with vacuum extractors (Hamilton et al., 2015).

• **Fig. 15.2** A soft, bell-shaped vacuum extractor (*top*) and a rigid, mushroom-shaped vacuum extractor (*bottom*). (Courtesy Cooper Surgical, Trumbull, CT, USA.)

The situations that indicate the use of the vacuum and the requirements that must be fulfilled for its correct use are identical to those for the obstetric forceps. The original device consisted of a metal cup but, currently, Silastic cups (flexible or semirigid) have replaced the metal varieties. Care must be taken in its application to ensure that an adequate seal with the fetal head has been created and that no maternal soft tissue is trapped between the suction device and the fetus. Traction is then applied to the fetal head in the line of the birth canal in an effort to assist delivery. It is also cautioned that rocking movements or torque to the cup should not be used. The premature infant (<34 weeks) is a relative contraindication to vacuum application. It is generally advised that no more than three detachments occur before attempts at vacuum extraction are abandoned (Ali and Norwitz, 2009).

In a laboratory experiment, Duchon et al. (1988) compared the maximum force at suggested vacuum pressures (550–600 mmHg) prior to detachment for different types of vacuum devices. They found that the average force of traction exerted before detachment ranged from 18 to 20 kg. This result is interesting to bear in mind when one considers the older data of Wylie, who estimated the average tractive force required for delivery of infants was 15.95 kg for a primigravida and 11.33 kg for a multipara (Wylie, 1963; Feingold et al., 1988) (Fig. 15.2).

The original vacuum device developed in the 1950s by the Swedish obstetrician Dr. Tage Malmström was a disc-shaped stainless steel cup attached to a metal chain for traction. Because of technical problems and lack of experience with this instrument, vacuum devices did not gain popularity in the United States until the introduction of the disposable cups in the 1980s. There are two main types of disposable cups, which can be made of plastic, polyethylene, or silicone. The soft cup is a pliable, funnel or bell-shaped cup, which is the most common type used in the United States. The rigid cup is a firm mushroom-shaped cup (M cup) similar to the original metal disc-shaped cup and is available in three sizes.

A metaanalysis of 1375 women in nine trials comparing soft and rigid vacuum extractor cups demonstrated that soft cups were more likely to fail to achieve a vaginal delivery, because of more frequent detachments (odds ratio [OR] 1.65, 95% confidence interval [CI] 1.19–2.29), but were associated with fewer scalp

injuries (OR 0.45, 95% CI 0.15–0.60) and no increased risk of maternal perineal injury (Hillier and Johanson, 1994). For example, the risk of scalp laceration with the rigid Kiwi OmniCup (Clinical Innovations, Murray, Utah) was reported to be 14.1%, compared with 4.5% using a standard vacuum device ($P = .006$). These and other authors concluded that hand-held soft bell cups should be considered for more straightforward occiput-anterior deliveries, and that rigid M cups should be reserved for more complicated deliveries, such as those involving larger infants, significant caput succedaneum (scalp edema), occiput-posterior presentation, or asynclitism.

The vacuum extractor is used in the United States, but is not free from neonatal injury. Other than superficial scalp lacerations or abrasions, the use of the vacuum has been associated with cephalhematoma and subgaleal hemorrhages.

Cephalhematoma occurs when the force created by the vacuum results in the rupture of diploic or emissary vessels between the periosteum and outer table of the skull; this fills the potential space that exists between the two with blood. Although cephalhematomas are often cosmetically alarming, they are limited to traveling along one cranial bone, because the firm periosteal attachments limit further extravasation of blood across suture lines. Thus large amounts of blood cannot usually collect in this space, and serious neonatal compromise from this bleeding is rare. In a randomized trial of continuous and intermittent vacuum application, Bofill et al. examined factors associated with increasing the risk of cephalhematoma; it was found that only asynclitism and traction time were independently related to this complication (Hartley and Hitti, 2005). There was a clear relationship between increasing time of vacuum application (up to 6 minutes) and cephalhematoma. Interestingly, Hartley and Hitti did not find a significant independent association of neonatal injury with continuous versus intermittent vacuum, or with decreasing gestational age or increasing birth weight. Furthermore, the number of detachments was not correlated with cephalhematoma. These results were further corroborated by Teng et al., who conducted a prospective observational study of 134 vacuum extractions and found that only increasing total duration of vacuum application was associated with neonatal injury (Feingold et al., 1988). Metaanalysis of randomized trials comparing vacuum to forceps extractions showed that vacuums are more likely to fail to deliver the baby and lead to increased rates of cephalhematoma and retinal hemorrhage (Fig. 15.3) (Vacca, 2007).

Subgaleal hemorrhage poses much more risk for the neonate. It occurs when emissary veins above the skull and periosteum rupture, with blood dissecting through the loose tissue underlying the cranial aponeurosis, unimpeded by suture lines. A tremendous amount of blood, potentially the entire neonatal blood volume (approximately 250–350 mL), can fill this space and thus can compromise the neonate's condition (Hillier and Johanson, 1994). Much of the literature about this rare complication of vacuum extraction was published in the 1970s and early 1980s, with few recent studies to detail associated risk factors. Plauche, in his classic paper published in 1979 on vacuum-related neonatal injury, identified only 18 cases of subgaleal hematomas among 14,276 cases of vacuum-assisted births, in contrast to a mean incidence of cephalhematoma of 6% (Keith et al., 1988). These morbidity estimates are derived from data that are approximately 30–40 years old; nevertheless, Teng et al. noted an incidence of cephalhematoma of 8%, and 0.7% for subgaleal hemorrhage in their more recent investigation, which agrees well with Plauche's estimates (Herbst and Källén, 2008). The incidence in the United States in the last two decades is unknown as there was no specific CPT code to

• **Fig. 15.3** A cephalhematoma is a hemorrhage that occurs under the periosteum of the skull and is thus confined to a defined space with limited capacity for expansion. (Adapted from Gilstrap LC, Cunningham FG, Hankins GDV, et al. *Operative Obstetrics*, ed. 2. Stamford, CT: Appleton and Lange; 2002.)

• **Fig. 15.4** A subgaleal hematoma spreads along subcutaneous soft tissue planes and has no immediate barrier to expansion, creating the potential for significant neonatal hemodynamic compromise. (Adapted from Gilstrap LC, Cunningham FG, Hankins GDV, et al. *Operative Obstetrics*, ed. 2. Stamford, CT: Appleton and Lange; 2002.)

distinguish subgaleal hemorrhage from cephalhematoma or other forms of minor scalp injury until after 2010.

A study from Australian investigators evaluated 37 cases of subgaleal hemorrhage at a single tertiary care center accrued over a period of 23 years, with an estimated prevalence of 1.54/10,000 total births. The finding was that this complication occurred most often in primigravidae, and that a large proportion of these infants (89.1% compared with 9.8% of the general control population) had an attempted vacuum extraction (Fig. 15.4) (Chadwick et al., 1996). Failed vacuum extraction has been identified as a risk factor for subgaleal hemorrhage when comparing infants born after a

successful vacuum extraction (OR 7.3, 95% CI 5.5–9.7) (Ahlberg et al., 2016).

The choice of which instrument to use, forceps or vacuum, is usually determined by the obstetric care provider, depending on the skill level and experience with either method. There have been several randomized trials exploring the instrument used for operative vaginal delivery (Meniru, 1996; O'Grady et al., 2002; Menacker and Martin, 2008; Prapas et al., 2009). The Cochrane Library has pooled the results from 10 randomized trials comparing neonatal morbidity and successful vaginal delivery between these two devices (Roberts et al., 2002). This analysis found that the vacuum was more likely than forceps to fail (OR 1.69, 95% CI 1.31–2.19) and was associated with a greater likelihood of cephalhematoma (OR 2.38, 95% CI 1.68–3.37) and retinal hemorrhage (OR 1.99, 95% CI 1.35–2.98). However, the overall serious complication rate was low, and there was no difference in long-term morbidity between groups (Johanson and Menon, 2000).

A significant problem with the use of vacuum extraction is the difficulty some providers experience in abandoning the procedure and opting for cesarean delivery. One of the best cohort studies found that 82% of successful vacuum extractions occurred with the first three pulls (Murphy and Koh, 2003). When more than three pulls were necessary, signs of trauma were present in 45% of babies. Without clear progress toward vaginal delivery, as evidenced by progressive descent with each pull, attempts at further vaginal birth are not supported by the literature.

Shoulder Dystocia

Shoulder dystocia is arguably the most dreaded complication in obstetrics. The problem posed by this entity is that although it is highly anticipated, it is unpredictable and can appear despite the most cautious measures taken to prevent it. *Shoulder dystocia* is defined as the delivery of the fetal head with an impaction of the fetal shoulder girdle against the pubic symphysis, making subsequent delivery either difficult or impossible without performing auxiliary delivery maneuvers. In some cases the posterior shoulder may be lodged behind the sacral promontory – a bilateral shoulder dystocia.

Once shoulder dystocia occurs, a series of maneuvers – which have never been tested in a prospective fashion, because of the sporadic and unpredictable nature of this complication – are used to resolve it. The first step to resolving shoulder dystocia is usually the McRoberts maneuver, which consists of hyperflexing the maternal thighs onto the abdomen. This maneuver flattens the pubic symphysis and sacral promontory and facilitates delivery of both the anterior and posterior shoulders. The only prospective randomized study of prophylactic McRoberts maneuver in anticipation of shoulder dystocia showed no benefit to this strategy (Beall et al., 2003). If the McRoberts maneuver is unsuccessful, the next intervention is typically applying suprapubic pressure to remove the anterior shoulder from its impacted state behind the pubic symphysis. If these two maneuvers fail, either rotational maneuvers or extraction of the posterior fetal arm are usually tried. The Woods screw rotational maneuver or the Rubin rotational maneuver is used in an attempt to rotate the infant's shoulders to relieve the impaction of the shoulder against the pubic bone. Alternatively, delivery of the posterior arm can be accomplished by inserting the operator's hand into the vagina and grasping the fetal wrist in the posterior arm and guiding it through the vaginal introitus. It is often necessary to perform an episiotomy to have sufficient room in the vagina to accomplish this maneuver. An alternative maneuver

to fetal manipulation is the all-fours position, or Gaskin maneuver. With this maneuver, the mother is moved from the lithotomy position to a hands and knees position. Next, the posterior fetal shoulder, which is now at the 12 o'clock position, is delivered with gentle downward traction. If the dystocia continues unresolved, the Zavanelli maneuver (cephalic replacement) can be performed. After the fetal head is rotated from occiput transverse to occiput anterior, it is flexed and pushed back in the birth canal, and the child is delivered by emergent cesarean section. McRoberts maneuver, suprapubic pressure, or both will relieve shoulder dystocia in more than 50% of instances. Cephalic replacement should be rarely necessary.

In the past few years greater attention has been focused on enhanced practitioner training for shoulder dystocia by means of simulation. Prior to the development of high-fidelity models for shoulder dystocia training, many obstetric birth attendants had never successfully performed maneuvers other than the McRoberts maneuver and suprapubic pressure. Draycott et al. (2008) published data showing that the annual compulsory multidisciplinary training of all attending obstetric physicians and nursing staff in Southmead Hospital in the United Kingdom reduced the incidence of fetal injury and brachial plexus injury within 3 years of introduction. Grobman et al. (2011) found similar reduction in brachial plexus injury recognizable at the time of birth after establishment of a standard protocol and simulation training of providers. Inglis et al. (2011) found similar results when shoulder dystocia training was introduced. At the current time, multidisciplinary team training with a standard protocol appears to offer the best strategy to minimize brachial plexus injury once shoulder dystocia has occurred.

The prevalence of shoulder dystocia varies depending on the population studied and the presence of various risk factors known to predispose women to this obstetric emergency. Estimates range from 0.2% to 1% in a low-risk population to 20% in higher-risk groups (Feingold et al., 1988; Hartley and Hittii, 2005; Herbst and Källén, 2008; Ali and Norwitz, 2009). Maternal obesity, fetal macrosomia, history of prior shoulder dystocia, and maternal diabetes mellitus are the most common associated variables, but are not of sufficient prognostic power to be clinically useful in predicting shoulder dystocia (Herbst and Källén, 2008; Ali and Norwitz, 2009).

Because shoulder dystocia has the potential to cause significant neonatal morbidity and mortality, efforts have been made to predict its occurrence; unfortunately, no clinical guidelines have been clinically tested or proved. Ultrasound examination is commonly used in patients with suspected fetal macrosomia or diabetes to detect large birth weight infants who might be more likely to suffer shoulder dystocia. Third-trimester sonographic examination has an accuracy of $\pm 10\%$ – 15% in the prediction of fetal weight and is thus not highly reliable (Feingold et al., 1988; Keith et al., 1988; Hillier and Johanson, 1994). In addition, if ultrasound examination were completely reliable, the fetal weight cutoff that would prompt an elective cesarean section has not yet been determined.

If practitioners use ultrasound to evaluate estimated fetal weight (EFW), then two strategies have been suggested to avoid shoulder dystocia: labor induction or cesarean section. A recently published randomized clinical trial in France based on ultrasound evaluation of EFW has clarified the risks and benefits of labor induction to avoid shoulder dystocia and subsequent fetal injury (Boulvain et al., 2015). In this trial 800 patients with EFWs greater than the 95th percentile for gestational age were randomized to either induction of labor or observation at 37–39 weeks' gestation. At study conclusion, shoulder dystocia was reduced from 8% to 4% (OR 0.47,

CI 0.26–0.86). Predetermined composite of fetal injury was also reduced from 6% to 2% (CI 0.15–0.71). There were, however, no brachial plexus injuries or deaths in either group. In addition, the occurrence of cesarean delivery was similar in both groups (28% induced vs 32% expectant management: OR 0.89, CI 0.72–1.09). Currently in the United States, labor induction prior to 39 weeks is an adverse quality metric and has financial consequences for both the hospital and obstetric provider. Whether this indication will gain acceptance as an exception to this quality metric remains to be determined.

Rouse et al. (1996) elaborated further on the use of ultrasound to prevent shoulder dystocia. In their decision analysis, they showed that if one chose to perform an elective cesarean section for all women without diabetes but who had sonographically predicted macrosomia (EFW >4000 g), 2345 cesarean sections would need to be performed to prevent one permanent brachial plexus injury. If the 4500-g cutoff were selected, 50% more cesarean deliveries would be needed to prevent one permanent brachial plexus injury. In the mother with diabetes, if one chose a cutoff of 4500 g or greater, 443 cesareans would need to be done to prevent one permanent injury, a tradeoff that most practitioners now believe is acceptable. The conclusions from this decision analysis have been borne out by several other investigators who have established that the risk of nerve injury certainly increases with rising birth weight, but the large number of macrosomic infants who have a normal, spontaneous vaginal delivery without sequelae does not justify a policy of elective cesarean for macrosomia alone in a nondiabetic population (Loucopoulos and Jewelewicz, 1982; Lipitz et al., 1989; Meniru, 1996; O'Grady et al., 2002; Roberts et al., 2002; Pondaag et al., 2004; Menacker and Martin, 2008). Some believe that an EFW of greater than 5000 g provides an acceptable cutoff in nondiabetic patients to offer elective cesarean.

The ideal management of shoulder dystocia would minimize the occurrence of permanent fetal injury or death. In the best systematic review of brachial plexus injury to date, the risk of permanent brachial plexus impairment, if recognizable at birth, was 15%–20% (Pondaag et al., 2004). In another study, a prospective investigation evaluated the natural history of recovery following a birth-related brachial plexus injury of infants referred to a tertiary care, multidisciplinary neurologic center. Enrollment required identification of injury in the newborn period, initial evaluation at the center between 1 and 2 months of age, and lack of antigravity movement in the shoulder or elbow persisting until 2 weeks of age. In this group of children subject to ascertainment bias (as those injuries resolving before 2 weeks of age would not have been included in the results), complete neurologic recovery was documented in 66%, 20% had minimal impairment, and 14% had persistent, severe weakness (Learman, 1998).

At present there is no universally accepted method to prevent shoulder dystocia. Previous studies have shown that operative vaginal delivery, especially vacuum delivery, of a fetus suspected to have macrosomia either clinically or sonographically could increase the risk of shoulder dystocia (Benedetti and Gabbe, 1978). Thus it seems wise to avoid difficult forceps or vacuum delivery if a patient is thought to have an infant weighing more than 4000 g, especially if she has diabetes or a past history of shoulder dystocia.

Prospective studies have shown that brachial plexus injury is related to the extent of provider-applied traction to the fetal head and neck (Mollberg et al., 2007). However, there is a large variation in the provider assessment of traction used in deliveries of infants with brachial plexus recognizable at birth (Mollberg et al., 2007). Several studies evaluating simulated shoulder dystocia measured

traction forces applied by the birth attendant (Allen et al., 1991; Crofts, 2007; Deering et al., 2011). Provider experience, gender, and body habitus were not associated with the amount of force applied during delivery. Family medicine providers applied more force than obstetrics/gynecology providers. A significant number of all providers (19/47, 40%) applied greater than 100 newtons to the fetal neck, a suggested but not proven threshold for brachial plexus injury (Deering et al., 2011).

Currently, delivery training emphasizes that only axial traction be applied to the fetal neck, which should minimize stretch on the brachial plexus during delivery. Unfortunately, some infants are injured with minimal or no force being applied to the fetal neck, which suggests that some injuries occur as a result of a combination of labor and the standard techniques used to deliver all infants and are therefore not provider-dependent (Deering et al., 2011).

The documentation of the events surrounding shoulder dystocia is important, as is the discussion of current status and future status of an infant delivered with a birth injury after shoulder dystocia. The recurrence risk of shoulder dystocia is approximately 10%–15%, which is similar to the risk of shoulder dystocia with a known fetal weight of 4500 g. Both obstetric and pediatric providers should debrief a shoulder dystocia event immediately after the delivery. Regardless of whether fetal injury has occurred, it is optimal for both obstetric and pediatric providers to discuss the delivery events and subsequent newborn treatment plans if necessary with the mother before discharge. The diagnosis of shoulder dystocia is an obstetric diagnosis made at the time of delivery, which is based upon delivery findings as defined above. This is not a diagnosis that should be made by the pediatric team or based on observations of the neonate after delivery.

Vaginal Breech Delivery

Three to four percent of all infants at term will present in the breech position at the time of delivery (Hickok et al., 1992). There are three main types of breech presentations: the footling breech has one (single footling) or both (double footling) lower extremities presenting; the frank breech has both thighs flexed, but legs extended; and the complete breech has both thighs and legs flexed. The vaginal delivery of a singleton footling breech carries attendant risks of cord prolapse and head entrapment, and the consensus among obstetricians is that this presentation should be delivered by cesarean section (unless the fetus is a second twin: see later discussion on [Twin Delivery](#)). The frank breech has a lower risk of these adverse events occurring and thus could potentially be delivered vaginally. The complete breech presentation will convert to frank or footling during labor, and the appropriate management scheme for delivery depends on which leading fetal part will descend.

The mechanics of vaginal breech delivery are as follows. The frame of reference for the presenting part is the sacrum (i.e., sacrum anterior, posterior, or transverse). In the absence of urgent fetal indications, the singleton breech is allowed to deliver passively with maternal expulsive efforts until the infant has been delivered past the umbilicus. At this point the legs are gently reduced, and the trunk and body are gently rotated to bring the sacrum anteriorly. With the appearance of the scapula below the maternal symphysis, the arms are then delivered by gently sweeping them across the chest. Every effort is then made to keep the neck from extending during the delivery of the after-coming head; this is accomplished during delivery of the body by an assistant exerting suprapubic pressure on the fetal head to keep it flexed. Once the body has

delivered, the delivery of the head is accomplished by either the Mauriceau–Smellie–Veit maneuver or with Piper forceps directly applied to the fetal vertex. In the Mauriceau–Smellie–Veit maneuver one hand extends along the posterior neck and occiput and applies pressure to prevent hyperextension, while the other hand gently applies downward traction against the maxilla to flex the head forward as the head is delivered. A free video demonstrating the vaginal breech delivery is available online at the WHO Reproductive Health Library: <http://apps.who.int/rhl/videos/>.

The feasibility of vaginal breech delivery and its safety have been the subject of much debate throughout the past half century. With the advent of safe, expedient cesarean delivery in the United States, many obstetricians have favored cesarean section as the method of choice for management of the breech presentation at term. However, even in institutions with availability for expedient cesarean deliveries, there are situations such as precipitous delivery, out-of-hospital delivery, severe fetal anomalies, fetal death, or a mother's preference for vaginal birth that make it essential for clinicians to maintain the skills needed for a vaginal breech delivery. The literature to support this point of view has produced conflicting conclusions, and its interpretation is consequently difficult. Unfortunately, there are only two randomized trials that have explored the question of which delivery route is best for the term singleton frank breech fetus (Collea et al., 1980; Hannah et al., 2000).

Collea et al. (1980) randomized 208 women with a singleton frank breech presentation at term to vaginal delivery or cesarean section; they found a low overall risk of permanent birth injury or neonatal morbidity in the vaginal delivery group, although the incidence of neonatal morbidity was higher in the vaginal delivery group. Of note, a majority of conditions listed as morbidities (hyperbilirubinemia, meconium aspiration, mild brachial plexus injury) had resolved by hospital discharge. In addition, decreased neonatal morbidity with cesarean section was offset by a striking increase in higher maternal risk in the operative group. It must be remembered that this study was published in 1980, and standards of maternal and neonatal care have changed dramatically since then.

Hannah et al. (2000) published a large, multicenter, multinational trial that randomized 2088 women at 121 centers in 26 countries to planned vaginal birth or planned elective cesarean section. Criteria for enrollment were frank or complete term singleton breech with no evidence of fetal macrosomia. The investigation was halted when preliminary results showed that there was significantly increased neonatal mortality and severe morbidity in the vaginal breech arm compared with the cesarean arm (5.0% vs 1.6%). This conclusion was not altered by the experience of the delivering obstetrician or maternal demographic factors such as parity and race. Maternal morbidity between both groups was comparable. The difference in outcome was even more striking in countries such as the United States, with a low national perinatal mortality rate (5.7% vs 0.4%).

Criticisms of this study are that the patients enrolled did not have computed tomography (CT) pelvimetry performed, which in some institutions is standard practice before considering a vaginal breech delivery. Furthermore, subjects did not have continuous fetal monitoring, but rather intermittent fetal auscultation every 15 minutes. In addition, the capability of various centers to perform emergent cesarean sections differed markedly, and this could have potentially affected the neonatal morbidity and mortality rate. Nevertheless, it is unlikely that another large study will ever be performed to examine this issue, and the ultimate results are difficult

to dispute given the excellent study design and adequate sample size.

The Term Breech Trial Collaborative Group published outcomes of children after planned cesarean birth versus planned vaginal birth for breech presentation at term. In this analysis they followed 923 of the 1159 enrolled subjects (79.6%) to 2 years of age. The risk of death or neurodevelopmental delay was no different between the planned cesarean section versus the planned vaginal groups (14 children [3.1%] vs 13 children [2.8%]; relative risk [RR] 1.09, 95% CI 0.52–2.30) (Hannah et al., 2000).

In addition, there are several large retrospective series describing neonatal outcomes with the vaginal approach, most of which suggest that vaginal delivery in carefully selected patients carries a low risk of long-term neonatal morbidity and mortality (Hillier and Johanson, 1994; Diro et al., 1999; Herbst and Källén, 2008; Vlemmix et al., 2014; Vistad et al., 2015). A recent metaanalysis assessing the risks of planned vaginal breech delivery versus planned caesarean section for term breech birth included studies between 1993 and 2014 and included 27 articles with a total sample size of 258,953 women and reported the relative and absolute risks of perinatal mortality and morbidity in relation to mode of delivery. They reported that the absolute risks of perinatal mortality, fetal neurologic morbidity, birth trauma, a 5-minute Apgar score less than 7, and neonatal asphyxia in the planned vaginal delivery group were 0.35%, 0.7%, 0.7%, 2.4%, and 3.3%, respectively. They concluded that perinatal mortality and morbidity in planned vaginal breech delivery was significantly higher than with planned caesarean delivery, which is consistent with the aforementioned authors (Berhan and Haileamlak, 2016). The truly interesting point raised by all these investigators is that, aside from the issue of cesarean versus trial of labor, singleton breech infants regardless of mode of delivery have an increased risk of morbidity compared with their vertex counterparts. Breech infants had higher incidences of neonatal intensive care unit (NICU) admissions, eventful hospital courses, hip dislocation, and traumatic morbidity (soft tissue trauma, fracture, facial nerve paralysis, and brachial plexus palsy). Thus both the obstetrician and pediatrician must be aware that the infant in breech presentation requires careful attention upon birth for the presence of these potential factors. Furthermore, the risk of developmental hip dysplasia is increased in infants born in breech presentation. The American Academy of Pediatrics (AAP) has a clinical practice guideline for early detection of developmental dysplasia of the hip in these infants (AAP, 2000).

Diro et al. (1999) evaluated 1021 term singleton breech deliveries occurring at their institution over a 4-year period. Infants with a clinically adequate pelvis and frank breech presentation with an EFW less than 3750 g were allowed a trial of labor. They found an overall cesarean rate of 85.6%; however, for women allowed to deliver vaginally, the success rate, defined as vaginal delivery, was 50% (19 of 38 patients) for nulliparous women and 75.8% (116 of 153 patients) for multiparous women. The length of NICU stay was higher for the group delivered vaginally (17.4% vs 12.1%; $P = .036$), but major morbidities between operative and vaginal delivery were not significantly different. Long-term outcome was not evaluated. Of note, the women in this cohort had pelvic dimensions evaluated clinically, and not by X-ray or CT pelvimetry, as has been performed in other studies.

Norwegian investigators examined the neonatal outcomes of singleton term breech deliveries from 1991 to 2011. They evaluated 30,681 singleton term breech deliveries identified using the Medical Birth Registry in Norway. They compared the planned vaginal delivery with the planned cesarean delivery across two time periods:

January 1991 to November 2000 and November 2000 to December 2011. They identified an increase in cesarean delivery from 34.4% to 51.3% across these study periods. They also found that early neonatal mortality in the first 0–6 days after delivery declined from 0.10% to 0.04% ($P = .04$). During the second time period, 30.7% of term breech presentations delivered vaginally. There were eight deaths in the planned vaginal and four in the planned cesarean groups, although the difference was not statistically significant (OR 2.11, 95% CI 0.64–7.01). Neonatal outcomes were significantly worse in the planned vaginal delivery groups across both time periods (Vistad et al., 2015).

The delivery of the vaginal breech is an emotional issue; physicians trained in the art of the vaginal breech delivery maintain that for an appropriately selected candidate, vaginal breech delivery has acceptable neonatal risk and has the advantage of sparing the mother significant operative morbidity. Proponents of cesarean delivery further state that the level of resident training in the art of the singleton vaginal breech delivery has markedly diminished, with most graduating senior residents having performed few such births. Nonetheless, many practitioners will be required to assist in vaginal birth of a breech infant in unplanned situations. The acquisition of skills necessary to competently perform this procedure may need to be learned and practiced with simulation-based training, because the opportunities for training in most residency programs are few. ACOG has recommended that the decision regarding the mode of delivery should depend on the experience of the healthcare provider. However, cesarean delivery will be the preferred mode of delivery for most physicians because of the diminishing expertise in vaginal breech delivery (ACOG, 2006). As will be discussed later in Multifetal Delivery, this statement does not apply to the vaginal delivery of a nonvertex second twin.

Multifetal Delivery

With the advent of in vitro fertilization and the sophisticated assisted reproductive technologies, the incidence of multifetal pregnancies has dramatically increased, particularly higher-order multiples. The incidence of twin gestations in patients undergoing in vitro fertilization is currently 20% in the United States (Scholten, 2015), and it is 1%–3% for higher-order multiples. As a result, the frequency of twin gestation in the United States has increased from 1/53 infants in 1980 to 1/30 infants in 2009 (Martin et al., 2013); twins now account for 3% of births. Of these, 80% are dizygotic and 20% are monozygotic. This 3% of births accounts for 17% of preterm births and approximately 25% of infants of low birth weight and very low birth weight. The perinatal mortality rate of twins is sevenfold that of singletons, of which a small fraction is due to problems during labor and at delivery. The mode of delivery for twins is well delineated by several studies, and the issues surrounding the choice of vaginal birth versus cesarean delivery are outlined in the following sections (Smith et al., 2005).

Twin Delivery

Vertex–Vertex

Approximately 40% of twin gestations will be in a vertex–vertex presentation prior to delivery (Arabin and Kyvernitakis, 2011). It is almost universally accepted that the appropriate method of delivery is vaginal if both twins are vertex. The first infant is delivered like a singleton infant. The second infant is delivered in a similar fashion, but care must be taken not to rupture membranes before the head is well engaged, because this may increase the risk of

cord accident. Of note, the delivery of the second twin does not necessarily occur immediately after the first.

Vertex–Nonvertex

Vertex–nonvertex presentation occurs 38.4% of the time prior to delivery (Arabin and Kyvernitakis, 2011). The first twin is usually delivered vaginally. The options for delivery of the second twin are as follows: cesarean section, breech extraction, or attempts at external cephalic version and vertex delivery of the second twin if successful. The optimal delivery choice for the second twin has been the subject of much controversy. Many obstetricians claim that cesarean section is the safest approach to the nonvertex twin, whereas others claim that vaginal delivery affords equivalent neonatal outcome, sparing the mother from an unnecessary surgical procedure (Usta et al., 2005). There is only one randomized trial including 60 twin deliveries of planned vaginal versus cesarean section in this situation. Maternal morbidity and hospital stay were increased in the surgical group, but there were no differences in neonatal outcome (Rabinovici et al., 1987).

Hogle et al. (2003) performed a metaanalysis to determine whether a policy of planned cesarean or planned vaginal birth is preferable for twins. They found only four studies with a total of 1932 infants that met their inclusion criteria. There were no significant differences in maternal morbidity, perinatal or neonatal mortality, or neonatal morbidity between the two groups. They did find significantly fewer low 5-minute Apgar scores in the planned cesarean group, principally because of a reduction among breech first twins. They concluded that, if twin A is vertex, “there is no evidence to support planned cesarean section for twins.” In contrast, Smith et al. (2005) published a retrospective cohort study of 8073 twin births after 36 weeks’ gestation in Scotland between 1985 and 2001. There was a death of either twin in two of 1472 (0.14%) deliveries by planned cesarean and in 34/6601 (0.52%) deliveries by other means ($P = .05$; OR for planned cesarean 0.26, 95% CI 0.03–1.03). They concluded that planned cesarean may reduce the risk of perinatal deaths of twins at term by 75% despite the lack of statistical significance in outcomes between the two groups. The data also suffer from the fact that 30 of the 36 deaths were in second twins, and there were no data regarding fetal presentation (Smith et al., 2007).

There are several large cohort studies examining the issue of feasibility and safety of total breech extraction of the nonvertex second twin. These studies have almost unanimously reached the similar conclusion that the neonatal outcome for nonvertex second twins delivered vaginally is similar to the vertex first twin, but is not statistically different from those second twins delivered by cesarean section, regardless of birth weight or gestational age (Feingold et al., 1988; Keith et al., 1988; Hillier and Johanson, 1994; Hartley and Hitti, 2005; Herbst and Källén, 2008; Ali and Norwitz, 2009). Hartley and Hitti (2005) conducted a retrospective analysis of birth certificates and fetal and infant death certificates for 5138 twin pairs selected from those born in Washington State from 1989 to 2001. They concluded that if prompt vaginal delivery of twin B does not occur, the benefits of vaginal delivery for twin A might not outweigh the risks of distress and low Apgar scores in twin B and vaginal plus cesarean delivery for the mother (Hartley and Hitti, 2005).

The available body of evidence supports attempts at vaginal delivery of the nonvertex second twin. Of course the responsible obstetrician must choose a management plan most compatible with his or her experience and training. For those not versed in the techniques of successful vaginal breech extraction, cesarean

delivery might be a more prudent plan. As in the case of the singleton vaginal breech, simulation training may play a role in the acquisition and maintenance of skills for safe vaginal breech birth (Deering et al., 2006).

In addition to cesarean delivery and total breech extraction, there is the option of external cephalic version (i.e., attempting to turn a nonvertex fetus to vertex by abdominal manipulation). Studies have shown that this option is associated with a higher failure rate at successful vaginal delivery and other complications (such as cord accident and malpresentation not amenable to vaginal delivery) when compared with primary breech extraction or cesarean section (Hillier and Johanson, 1994; Learman, 1998).

If the vaginal approach is chosen, once the first twin is delivered the obstetrician inserts a hand into the uterine cavity and, under sonographic guidance if necessary, finds the feet of the second twin. Once the feet are firmly grasped, they are brought down into the vagina, and the membranes are then ruptured. Traction is applied to the fetus along the pelvic curve; once the body has been delivered through the introitus, delivery of the arms, shoulders, and after-coming head proceed in a fashion similar to that of a singleton breech.

Nonvertex–Nonvertex

The most uncommon combination for presenting position at birth is nonvertex–nonvertex, which occurs 19.1% of the time (Arabin and Kyvernitakis, 2011). Because of the theoretical risk of interlocking twins, as well as the recent data showing the greater morbidity for the singleton vaginal breech (see the preceding discussion), cesarean section is the recommended choice for delivery of the nonvertex–nonvertex presentation.

Monochorionic, Monoamniotic Twins

Monochorionic, monoamniotic twins share a single intraamniotic space and thus have a higher risk of cord and extremity entanglement during the course of delivery. It is commonly accepted that the optimal mode of delivery is a planned cesarean section before labor ensues.

Higher-Order Multiple Gestations

Most perinatologists would suggest cesarean delivery for triplets and higher-order multiples (Lipitz et al., 1989). Although this practice is common, the data mandating cesarean delivery are far from conclusive.

A Dutch study compared the outcomes of triplets delivered vaginally and abdominally at two institutions (Learman, 1998). One hospital favored cesarean section, whereas, at another, trial of labor was offered to all appropriate candidates. The success of vaginal delivery was relatively high (34 of 39 women [87%]). There was a higher incidence of neonatal mortality and postdelivery depression (as estimated by Apgar score) in the hospital favoring operative delivery compared with the vaginal delivery group. The biases inherent in this study are obvious, although the reported findings have been corroborated by several other reports from single institutions that offer trial of vaginal delivery to triplet gestations (Meniru, 1996; O’Grady et al., 2002; Menacker and Martin, 2008). Vintzileos et al. (2005) attempted to estimate the risks of stillbirth and neonatal and infant deaths in triplets, according to mode of delivery; they used the “matched multiple birth” data file that was composed of triple births that were delivered in the United States during 1995 through 1998 and found that 95% of all triplets were delivered by cesarean delivery. Vaginal delivery (all vaginal)

was associated with an increased risk for stillbirth (RR 5.70, 95% CI 3.83–8.49) and neonatal (RR 2.83, 95% CI 1.91–4.19) and infant (RR 2.29, 95% CI 1.61–3.25) deaths. They concluded that cesarean delivery of all three triplet fetuses is associated with the lowest neonatal and infant mortality rate and that vaginal delivery among triplet gestations should be avoided (Vintzileos et al., 2005). Most of the data on triplet births consist of small cohort studies and not randomized trials, and the possibility of type II or beta errors exists in the interpretation of many of these studies (Feingold et al., 1988; Keith et al., 1988). Thus delivery of triplet gestations vaginally while not an unreasonable approach has nearly disappeared from the practice of modern obstetrics in favor of routine cesarean delivery. Currently, quadruplets and other higher-order multiples are usually delivered by cesarean section (Ron-El et al., 1981).

Vaginal Birth After Cesarean: Neonatal Concerns

The overall cesarean delivery rate in the United States increased 60% from 1996 to 2009, from 20.7% to 32.9%. Since 2009, the rate has declined slightly to 32.7% in 2013, and nearly one-third of births continue to be delivered by cesarean each year (Hamilton, 2014). Surgery carries the maternal risks of increased blood loss, prolonged hospital stay, and longer recovery time compared with vaginal delivery. During the 1980s to 1990s, efforts were made to encourage women to attempt a trial of labor after a prior cesarean delivery because the success rates of a VBAC are reasonable, varying from 60% to 80%, depending on the indications for the prior cesarean delivery (Mozurkewich and Hutton, 2000).

Whereas VBAC rates remain relatively high in the United Kingdom at 33% (range 6%–64%), the rates are decreasing rapidly in the United States, from a high of 28.3% in 1996 to less than 1% in 2006 (Fang and Zelop, 2006; Caughey, 2009). This decrease occurred primarily because VBAC can result in uterine dehiscence, in which the prior scar asymptotically separates or, more seriously, uterine rupture occurs. A full discussion of VBAC, the studies supporting its safety, and the controversies surrounding its feasibility is beyond the scope of this chapter, and the interested reader is urged to consult *Williams Obstetrics*, 24th ed, for further details. This discussion instead focuses on neonatal risks from VBAC, particularly from its most dreaded complication, uterine rupture.

Studies have uniformly shown a risk of uterine rupture with VBAC on the order of 0.5%–1% (Feingold et al., 1988; Caughey, 2009). A large, retrospective study evaluated 20,095 women with a history of prior cesarean delivery and found that rupture risk was 0.16% if the woman elected for a repeat cesarean delivery; 0.52% if VBAC occurred as a result of spontaneous labor; 0.77% if labor was induced without prostaglandins; and 2.5% if labor was induced with prostaglandins (Feingold et al., 1988). Thus VBAC carries the lowest risk if labor is spontaneous. However, it is currently a well-accepted practice to induce and augment labor during a VBAC using mechanical dilation and/or oxytocin as the risk of uterine rupture remains less than 1%. The use of prostaglandins is not recommended during any portion of the labor process in patients with a prior uterine scar because of the increased risk of uterine rupture.

There are few large, well-designed studies specifically evaluating neonatal rather than maternal outcomes after VBAC. Kamath et al. (2009) performed a retrospective cohort study of 672 women who had one prior cesarean section and then underwent a trial of labor. They found that infants born by cesarean delivery had higher

rates of admission to the NICU (9.3% compared with 4.9%) and higher rates of oxygen supplementation for delivery room resuscitation (41.5% compared with 23.2%).

Yap et al. (2001) retrospectively evaluated 38,027 deliveries occurring at a single tertiary care institution and found 21 cases of uterine rupture; 17 occurred after a history of a prior cesarean delivery. The two neonatal deaths that occurred were a result of either prematurity (23-week-gestation fetus) or multiple congenital anomalies. All liveborn infants were discharged from the hospital without neurologic sequelae. Thus the ultimate neonatal outcome despite uterine rupture was favorable. However, all deliveries occurred in a tertiary care institution with readily available obstetric anesthesiologists, neonatologists, and obstetricians. Most deliveries after diagnosis of rupture occurred within 26 minutes.

A third group of investigators retrospectively identified 99 cases of uterine rupture occurring over a period comprising 159,456 births (Hillier and Johanson, 1994). Thirteen of these ruptures occurred before the onset of labor. There were six neonatal deaths, but four of these occurred in women with uterine rupture at admission and thus were never given a trial of labor. There were five cases of perinatal asphyxia, but once again it is not detailed whether these occurred in women allowed a trial of labor or in those who had ruptured on presentation to the hospital. Moreover, many of these women had an undocumented prior scar, which in some institutions would warrant an elective repeat cesarean section. The aforementioned study evaluating 20,095 women with a prior cesarean delivery and their subsequent risk of rupture found a neonatal mortality of 5.5% (Lydon-Rochelle et al., 2001). However, because this was a population-based study, it was not specified whether these deliveries occurred in tertiary care institutions with the capability of performing emergent operative rescue procedures in the event of uterine rupture.

Finally, Fang and Zelop (2006) reviewed all of the literature to date with regard to adverse neonatal outcomes after VBAC and found that the combined rates of intrapartum stillbirth and neonatal death were not statistically different between those electing trial of labor and those electing repeated cesarean section. Thus the true neonatal risk of VBAC, especially in the event of uterine rupture, cannot be precisely estimated at the current time. There are no studies adequately evaluating long-term outcomes of surviving infants after uterine rupture (Fang and Zelop, 2006).

It appears that the risk of uterine rupture after a prior cesarean delivery is low, but this risk increases when labor is induced with prostaglandins. It is appropriate to offer women VBAC, but they must be counseled carefully about the potential risk of uterine rupture. Careful documentation of the informed consent and labor management must be completed. Moreover, VBAC should occur in delivery facilities capable of rapidly performing an emergent cesarean section, because this improves the likelihood of minimizing adverse neonatal sequelae.

Cord Accidents

The term *cord accident* usually refers to adverse events affecting the fetus that occur as a result of a problem with the umbilical cord. This heterogeneous term encompasses umbilical cord prolapse, in which the cord delivers through the cervix and compression by a fetal part results in a significantly increased risk of asphyxia; it also includes such entities as cord entanglements or “true knots,” which can lead to fetal compromise.

The incidence of such events is not clearly known, because the diagnosis is often one of exclusion. One large population-based

study compared 709 cases of cord prolapse occurring among 313,000 deliveries to matched controls and found that low birth weight, male sex, multiple gestations, breech presentation, and congenital anomalies all increased the risk of umbilical cord prolapse (Ali and Norwitz, 2009). Not surprisingly, cord prolapse was associated with a high neonatal mortality rate (10%), which was reduced if cesarean rather than vaginal delivery was performed.

The standard of care in cases of cord prolapse is to proceed immediately with cesarean section as quickly as possible while an assistant elevates the presenting fetal part with a hand in the vagina to prevent compression of the umbilical cord. It is also of paramount importance to have appropriate pediatric support available at the time of delivery, because the newborn is likely to be depressed and require resuscitation.

As a clinical entity, cord accident (or in utero compromise), secondary to entanglement of the umbilical cord, is difficult to understand. Often in cases of in utero fetal demise (IUFD), a diagnosis or cause of fetal death is never found. It is tempting to attribute the demise to an event that compromises umbilical blood flow to the developing fetus, but the literature on this subject is scarce. HersHKovitz et al. (2001) identified 841 cases of true knots from a population of 69,139 deliveries (for a prevalence of 1.2%) and in a case-controlled study found that grand multiparity (>10 deliveries), chronic hypertension, history of genetic amniocentesis, male gender, and umbilical cord prolapse were all independently associated with true knots of the umbilical cord. The presence of a true knot was associated with both IUFD and a greater likelihood of cesarean delivery (HersHKovitz et al., 2001).

Obstetric Analgesia and Anesthesia

MARK D. ROLLINS AND MARK A. ROSEN

KEY POINTS

- Labor results in significant pain for many women that is individualized, dynamic, and unpredictable.
- Although the effects of obstetric analgesia and anesthesia on the fetus and neonate are typically benign, there is potential for adverse neonatal effects.
- During pregnancy, labor, and delivery, women undergo fundamental changes in anatomy and physiology that affect all organ systems, significantly alter pharmacokinetic and pharmacodynamic responses to many drugs commonly used in anesthesia, and have important implications for anesthetic administration.
- Opioids are the most commonly used systemic medications for labor and delivery, but are administered with limitations on both dose and timing because they readily cross the placenta and are associated with a risk of neonatal respiratory depression in a dose-dependent fashion.
- Neuraxial analgesia (epidural, spinal, and combined spinal–epidural techniques) is widely used and the most effective method for labor analgesia. Epidural labor analgesia is a catheter-based technique that provides continuous analgesia during labor using administration of medication into the epidural space. Neuraxial anesthesia does not affect the length of the first stage of labor or increase the risk for cesarean delivery but has been associated with an increased use of forceps or vacuum for vaginal delivery.
- For the patient without an epidural catheter, spinal anesthesia is the most common regional anesthetic technique used for cesarean delivery. Use of general anesthesia for cesarean delivery is typically reserved for situations where neuraxial anesthesia is contraindicated or emergent delivery is needed.

Labor results in significant pain for many women that is individualized, dynamic, and unpredictable. Documented attempts to help relieve labor pain date back to early recorded history, but primitive efforts were mainly based on ineffective techniques of distraction, counter-stimulation, suggestion, or use of herbal remedies. Modern techniques for labor analgesia and obstetric anesthesia, essential for operative delivery, provide an effective and safe alternative to women seeking pain-free childbirth. Although the effects of obstetric analgesia and anesthesia on the fetus and neonate are typically benign, there is potential for adverse effects. This chapter introduces some of the scientific background and clinical techniques used in providing obstetric analgesia and anesthesia, as well as some of the potential maternal and neonatal complications.

History of Obstetric Anesthesia

Modern obstetric anesthesia began in Edinburgh, Scotland, on January 19, 1847, when a professor of obstetrics, James Young Simpson, used diethyl ether to facilitate child delivery 3 months after Morton's historic demonstration of the anesthetic properties of ether at the Massachusetts General Hospital in Boston ([Longfellow and Wagenknecht, 1956](#)).

During the second half of the 20th century, anesthesiologists made significant advances in techniques and improved safety for delivering labor analgesia. Hingson and Edwards (1943) developed the continuous caudal catheter that preceded development of the epidural catheter. Virginia Apgar (1953) initially proposed a simple neonatal scoring system as a guide for evaluating the effects of obstetric anesthesia and later as a guide for neonatal resuscitation. Other early pioneers in the emerging specialty of obstetric anesthesia were Gertie Marx (1958), Sol Shnider (1963), and John Bonica (1967). They helped to characterize the normal changes in maternal physiology related to pregnancy, confirm the safety and efficacy of obstetric analgesia, determine the effects of these techniques on uterine blood flow and placental transfer of anesthetic agents, and evaluate the effects of these techniques and agents on newborn well-being.

Anatomy of Labor Pain

Contraction of the uterus, dilatation of the cervix, and distention of the perineum cause pain during labor and delivery. Somatic and visceral afferent sensory fibers from the uterus and cervix travel with sympathetic nerve fibers to the spinal cord ([Fig. 16.1](#)). These fibers pass through the paracervical tissue and course with the hypogastric nerves and the sympathetic chain to enter the spinal cord at nerve roots in the lower thoracic and upper lumbar segments (T10 to L1). During the first stage of labor (cervical dilation), the majority of painful stimuli are the result of afferent nerve impulses from the lower uterine segment and cervix, as well as contributions from the uterine body causing visceral pain (poorly localized, diffuse, and usually described as “a dull but intense aching”). The pain increases in severity as the first stage progresses. These nerve cell bodies are located in the dorsal root ganglia of levels T10 to L1. During the second stage of labor (pushing and expulsion), afferents innervating the vagina and perineum cause somatic pain (well localized and typically described as “sharp”). These somatic impulses travel primarily via the pudendal nerve to dorsal root ganglia of

• **Fig. 16.1** Parturition Pain Pathways. Nerves that accompany sympathetic fibers and enter the neuraxis at the T10, T11, T12, and L1 spinal levels carry afferent pain impulses from the cervix and uterus. Pain pathways from the perineum travel to S2, S3, and S4 via the pudendal nerve. (From Miller RD, Pardo MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Elsevier Saunders; 2011.)

the nerve roots in the sacrum (S2 to S4). Pain during this stage is caused by distention and tissue ischemia of the vagina, perineum, and pelvic floor muscles, associated with descent of the fetus into the pelvis and delivery. Neuraxial analgesic techniques that block levels T10 to L1 during the first stage of labor must be extended to include S2 to S4 for effective pain relief during the second stage of labor.

Changes in Maternal Physiology and the Implications

During pregnancy, labor, and delivery, women undergo fundamental changes in anatomy and physiology. These alterations are caused by changing hormonal activity, biochemical shifts associated with increasing metabolic demands of a growing fetus, placenta, and uterus, and mechanical displacement by an enlarging uterus (Cheek et al., 2002; Parer et al., 2002).

Maternal Circulatory System

Hypotension can occur when a pregnant woman is in the supine position because of compression of the vena cava by the gravid uterus. Significant aortoiliac artery compression occurs in 15%–20% of parturients and vena caval compression is universal, often as early as 13–16 weeks' gestation. Therefore supine positioning is avoided during anesthetic administration in the second and third trimesters. Significant lateral tilt is used in all cesarean deliveries and frequently during labor analgesia to help preserve uterine blood flow. Vena caval compression also contributes to lower extremity venous stasis and increased risk of thromboembolus.

Cardiac output increases during pregnancy, reaching an output 50% greater than the prepregnant state by the third trimester. During labor, maternal cardiac output increases during the first and second stages, reaching an additional 40% above prelabor values in the second stage (Robson et al., 1987). Each uterine

contraction results in the autotransfusion of 300–500 mL of blood back into the maternal central circulation. The greatest increase in cardiac output occurs immediately after delivery, when values can increase as much as 75% above predelivery levels. This abrupt increase in cardiac output is secondary to the loss of aortic caval compression, autotransfusion from the contracted uterus, and decreased venous pressure in the lower extremities (Kjeldsen, 1979).

Physiologic (dilutional) anemia of pregnancy occurs as a result of a greater increase in plasma volume (45%) than in red blood cell volume (20%) by term. Average blood loss at delivery – approximately 500 mL for vaginal delivery and 1000 mL for cesarean delivery – is well tolerated because of the expanded blood volume of pregnancy and autotransfusion (about 500 mL) from the contracted uterus after delivery (Cheek et al., 2002).

Maternal Airway and Respiratory Systems

During pregnancy, the maternal airway has significantly increased mucosal edema and tissue friability throughout the pharynx, larynx, and trachea. These changes make laryngoscopy and intubation more challenging. In addition, the presence of comorbidities such as preeclampsia, upper respiratory tract infections, and the active pushing and increased venous pressure during the second stage further exacerbate airway tissue edema (Munnur et al., 2005).

At term, minute ventilation is increased approximately 50%, oxygen consumption is increased by more than 20%, and functional residual capacity is decreased by 20%. The combination of these changes (increased oxygen consumption and decreased oxygen reserve) results in a state promoting rapid desaturation during periods of apnea. The changes in both airway and respiratory physiology during pregnancy make ventilation and intubation more difficult and increase the potential for complications with induction of general anesthesia. A current multi-institutional database of adverse obstetric anesthesia events notes that rates of failed intubation are approximately 1:533, although none of the ten failed obstetric intubations in the study resulted in maternal mortality (D'Angelo et al., 2014).

Maternal Gastrointestinal System

The gravid uterus increases intragastric pressure and causes the stomach and esophagus to reposition, resulting in decreased competence of the esophageal sphincter. Elevated progesterone and estrogen levels further reduce esophageal sphincter tone. Consequently, most pregnant women experience symptoms of gastric reflux (Marrero et al., 1992). Furthermore, gastric emptying is delayed by active labor and administration of opioids. Delayed gastric emptying and decreased competence of the esophageal sphincter cause an increased risk of pulmonary aspiration with induction of general anesthesia, which has important implications for airway management that are discussed in detail in the General Anesthesia section.

Uterine and Fetal Circulation

Uterine weight and blood flow increase throughout gestation from approximately 100 mL/min before pregnancy to approximately 700 mL/min (10% of cardiac output) at term gestation, with 50%–80% of the uterine blood flow perfusing the intervillous space (placenta) and 20%–50% supporting the myometrium. Uterine vasculature has limited autoregulation and remains (essentially) maximally dilated under normal conditions during pregnancy.

Maternal uterine blood flow decreases as a result of either reduced uterine arterial perfusion pressure or increased arterial resistance. Decreased perfusion pressure can result from systemic hypotension secondary to reduced cardiac preload from hypovolemia, aortic caval compression, or significant decreases in vascular resistance from the initiation of neuraxial anesthesia or induction of general anesthesia. Uterine perfusion pressure can also decrease from increased uterine venous pressure associated with vena caval compression (e.g., supine position), uterine contractions (particularly uterine hypertonus by oxytocin hyperstimulation), or a significant increase in intra-abdominal pressure (pushing during second stage or seizure activity). Despite these potential effects, phenylephrine (α -adrenergic) is useful for treating maternal hypotension secondary to neuraxial anesthesia, and it has been demonstrated to result in less fetal acidosis and base deficit compared with treatment with ephedrine (primarily β -adrenergic) in many clinical trials (Lee et al., 2002; Ngan Kee et al., 2009; Smiley, 2009). If treated promptly, transient maternal hypotension does not lead to fetal depression or neonatal morbidity.

Analgesic Options for Labor and Vaginal Delivery

The pain of labor is highly variable and described by many women as severe. Factors influencing the patient's perception of labor pain include duration of labor, maternal pelvic anatomy in relation to fetal size, use of oxytocin, parity, participation in childbirth preparation classes, fear and anxiety about childbirth, attitudes about and experience of pain, and coping mechanisms. The choice of analgesic method resides primarily with the patient. The medical condition of the parturient, stage of labor, urgency of delivery, condition of the fetus, and availability of qualified personnel are also factors. Many different techniques are available to alleviate labor and delivery pain, and none appears to increase the risk of cesarean delivery (Wong et al., 2005; American College of Obstetrics and Gynecology [ACOG], 2006; Sng et al., 2014; Practice Guidelines for Obstetric Anesthesia, 2016).

Analgesia refers to pain relief without loss of consciousness; regional analgesia denotes partial sensory blockade in a specific area of the body, with or without partial motor blockade. Regional anesthesia is the loss of sensation, motor function, and reflex activity in a limited area of the body. General anesthesia results in the loss of consciousness, and the goals for providing general anesthesia typically also include, amnesia, analgesia, and skeletal muscle relaxation.

Techniques for labor analgesia must be safe for both mother and fetus and individualized to satisfy the analgesic requirement and desires of the parturient; they also must accommodate the changing nature of labor pain and the evolving, varied course of labor and delivery (e.g., spontaneous vaginal delivery, instrumentally assisted vaginal delivery, and cesarean delivery). The current approaches to pain relief are outlined in [Box 16.1](#).

Nonpharmacologic Analgesia

There are a variety of nonpharmacologic techniques for labor analgesia. Many seem to reduce labor pain perception, however most lack the rigorous scientific methodology for the useful comparison with pharmacologic methods. Although data are limited, acupuncture, acupressure, transcutaneous electrical nerve stimulation, relaxation, and massage all demonstrate a modest analgesic

benefit during labor (Arendt and Tesmer-Tuck, 2013). Other techniques such as hypnosis and intradermal water injections have not been shown to be more effective than placebo. A metaanalysis reviewing the effectiveness of a support individual (e.g., family member, doula) noted that parturients with a support individual used fewer pharmacologic analgesia methods and had a decreased length of labor, less dissatisfaction, and a lower incidence of operative deliveries (Hodnett et al., 2012).

Systemic Medications

Opioids are the only commonly used systemic medications for labor and delivery, but are administered with limitations on both dose and timing because they readily cross the placenta and are associated with a risk of neonatal respiratory depression in a dose-dependent fashion. Although pain relief from the administration of systemic opioids is frequently inadequate for the duration of labor, this option can be beneficial for short-term analgesia, particularly in early labor. Opioids are inexpensive, easy to administer, and do not require a trained anesthesia provider. However, they have a high rate of maternal side effects (sedation, respiratory depression, dysphoria, nausea, pruritus), can decrease fetal heart rate (FHR) variability and fetal movements, and carry a potential risk of neonatal respiratory depression and changes in neurobehavior. Systemic administration of opioids at doses that are safe for mother and newborn provides some pain relief but does not have the analgesic efficacy of regional techniques. Systemic opioids are recommended for administration in small doses, with minimization of repeated dosing to reduce the accumulation of drug and metabolites in the fetus. Larger doses would risk excessive maternal sedation, maternal respiratory depression, loss of protective airway reflexes, newborn respiratory depression, and impairment of both early breastfeeding and newborn neurobehavior.

Opioids differ in pharmacokinetics, pharmacodynamics, method of elimination, and the presence of active metabolites, but all readily cross the placental barrier through passive diffusion. Systemic opioids are most useful for patients with minimal to moderate pain, precipitous labor, or contraindications to neuraxial blockade, such as a coagulopathy.

Meperidine remains the most widely used opioid worldwide. Maternal half-life of meperidine is 2–3 hours, with the half-life in the fetus and newborn being significantly greater and more variable at values between 13 and 23 hours (Kuhnert et al., 1979). In addition, meperidine is metabolized to an active metabolite (normeperidine) that can significantly accumulate after repeated doses. With increased dosing and a shortened time interval between dose and delivery, there is greater neonatal risk of decreased Apgar scores, lowered oxygen saturation, prolonged time to sustained respiration, abnormal neurobehavior, and more difficulty initiating successful breastfeeding (Nissen et al., 1997).

Morphine was used more frequently in the past, but currently is rarely used. Like meperidine, it has an active metabolite (morphine-6-glucuronide) and a prolonged duration of analgesia (3–4 hours). The half-life is longer in neonates compared with adults, and it produces significant maternal sedation.

Fentanyl is a synthetic opioid with a short duration of action (approximately 30 minutes), no active metabolites, and a ratio of fetal to maternal plasma concentrations of approximately 1:3. In small intravenous (IV) doses of 50–100 µg over an hour there were no significant differences in Apgar scores, respiratory depression, or neurobehavior scoring compared with newborns of mothers who did not receive fentanyl (Rayburn, Rathke, et al., 1989). In addition, a comparison of equianalgesic doses of IV fentanyl compared with IV meperidine demonstrated a decreased frequency of maternal nausea, vomiting, and prolonged sedation in the fentanyl group (Rayburn, Smith, et al., 1989). In addition, neonates whose mothers received meperidine required naloxone more often compared with the fentanyl-exposed infants.

Remifentanyl, an ultra-short-acting opioid rapidly metabolized by nonspecific serum esterases, is significantly metabolized by the fetus, with umbilical artery:vein ratios of approximately 0.3 (Kan et al., 1998). Remifentanyl administered by a patient-controlled analgesia (PCA) device is an analgesic option for women who have contraindications to neuraxial blockade. The primary benefit of choosing this rapidly metabolized drug is to minimize opioid-related side effects on the neonate. Remifentanyl can be used effectively for labor with PCA dosing, but it is difficult to achieve satisfactory analgesia without significant potential of maternal respiratory depression, and therefore requires more intensive monitoring and nursing. Consequently, it is typically reserved for patients with contraindications to epidural anesthesia (Van de Velde and Carvalho, 2016). In a prospective randomized controlled trial comparing the effectiveness of epidural analgesia with a remifentanyl PCA with optimized settings, epidural analgesia was significantly more effective than PCA with regard to labor pain; more sedation and hemoglobin desaturation were noted during remifentanyl analgesia, but there was no difference between groups in fetal and neonatal outcomes (Volmanen et al., 2008). A more recent equivalence trial performed between remifentanyl PCA and epidural analgesia found remifentanyl was inferior to epidural analgesia for satisfaction of pain relief and pain relief scores (Freeman et al., 2015).

Inhaled Nitrous Oxide

The use of nitrous oxide is widespread in Canada, Australia, Scandinavia, the UK, and other parts of the world, and recently its use has increased in the United States (Likis et al., 2014). Nitrous oxide is a weak analgesic but can provide satisfactory pain relief and anxiolysis for some parturients. It is inhaled intermittently in a 50% mixture with oxygen and provides satisfactory labor analgesia for some women, but is a much less effective analgesic compared with epidural analgesia. Side effects are minimal, with nausea, dizziness, and drowsiness among the most common. Uterine contractility is not affected and the degree of maternal cardiovascular and respiratory depression is very mild. At a 50% concentration (without coadministration of opioids or other sedatives), nitrous oxide is insufficient to cause unconsciousness or loss of protective airway reflexes. Nitrous oxide provides a safe analgesic option for laboring women when administered with appropriate equipment by trained personnel, which is essential to ensure safety (i.e., limiting the nitrous oxide concentration, avoiding administration of a hypoxic mixture, avoiding coadministration of other agents)

(Camann et al., 2015). It can be used during the first, second, or third stage of labor. The effects of nitrous oxide are quickly reversed with discontinuation because of its rapid respiratory elimination, and it does not cause neonatal depression, regardless of duration of administration (Rosen, 2002a). When administered with appropriate scavenging equipment, there does not appear to be concern regarding occupational exposure. Despite its historical use, rigorous scientific studies are lacking to adequately assess its overall efficacy, safety, and long-term effects on the fetus and newborn (King and Wong, 2014).

Neuraxial (Regional) Analgesia

Neuraxial analgesia, including epidural, spinal, and combined spinal–epidural (CSE) techniques, is the most widely used method for labor analgesia in the United States (Bucklin et al., 2005). Neuraxial techniques typically involve epidural and spinal administration of local anesthetics and often the coadministration of epidural and spinal opioid analgesics. Administration of other adjuvants, such as epinephrine and clonidine, also can decrease the dose of local anesthetics required for analgesia but such adjuvants are used much less frequently than opioids and do not appear to offer a significant advantage (Aveline et al., 2002; Polley et al., 2002).

Neuraxial Local Anesthetics

Local anesthetics reversibly block nerve impulse conduction via voltage-gated sodium channels. Their chemical structures are secondary or tertiary amines, which are weak bases. Local anesthetics differ in their onset, peak plasma concentration, potency, and duration based on their lipid solubility, protein binding, site of injection, and concentration. Vascular absorption of local anesthetics limits the safe dose that can be administered. Bupivacaine and ropivacaine are the most commonly used local anesthetics for labor analgesia and are extremely safe when appropriately dosed for epidural or intrathecal administration. An accidental, large intravascular dose of any local anesthetic can result in significant maternal morbidity or mortality.

As with all drugs, placental transfer is determined by molecular size, lipid solubility, protein binding, charge, and maternal drug concentration. Local anesthetics are highly lipid soluble and have a low ionized fraction. However, the lower pH of the fetus has the potential to increase the fraction of ionized molecules, decrease lipid solubility, and result in ion trapping. Therefore in an acidotic fetus, higher concentrations of local anesthetic can accumulate (ion trapping) and result in decreased neonatal neuromuscular tone. If a direct intravascular or intrafetal injection of local anesthetics occurs, significant toxicity and depression can develop, signified by bradycardia, ventricular arrhythmia, and severe cardiac depression with acidosis.

Neuraxial Opioids

Epidural administration of lipid-soluble opioids (e.g., sufentanil, fentanyl) provides rapid analgesia equivalent to that of systemic administration but remains inferior to that of dilute concentrations of local anesthetics. When lipid-soluble opioids are coadministered with local anesthetics in the epidural space, they decrease the total local anesthetic dose required and lower the minimum local anesthetic concentration needed to achieve adequate labor analgesia (Lyons et al., 1997; Buyse et al., 2007). The most common maternal

side effects of conventional doses of epidural fentanyl or sufentanil are pruritus and nausea. Although typical doses used for labor analgesia do not adversely affect the neonate, the potential for respiratory depression is a function of the amount and timing of epidural opioid administered because much of the opioid administered in the epidural space crosses to the maternal plasma.

Subarachnoid (i.e., spinal, intrathecal) opioid injections provide effective maternal labor analgesia. Analgesic effects of spinal opioids are more potent than epidural or systemic administration, but are of limited duration (≤ 2 hours). Spinal fentanyl or sufentanil administration is often performed as part of a CSE technique (discussed in the following section). Intrathecal opioids are often combined with small doses of local anesthetic (e.g., 2.5 mg bupivacaine), decreasing the dose of opioid needed and the incidence of pruritus and nausea (Wong et al., 2000). Use of high-dose intrathecal opioids (e.g., sufentanil 7.5 μg) is associated with increased risk of fetal bradycardia and severe pruritus, even without the presence of hypotension (Van de Velde, 2005). The mechanism for fetal bradycardia is uncertain, but may be from uterine hyperactivity following the rapid analgesia. A systematic review of studies comparing intrathecal opioids with other methods of labor analgesia noted an increase in fetal bradycardia (odds ratio [OR] 1.8, 95% confidence interval [CI] 1.0–3.1) and increased maternal pruritus (relative risk [RR] 29.6, 95% CI 13.6–64.6), but no increased risk of cesarean delivery because of FHR abnormalities (Mardirossoff et al., 2002).

Neuraxial Techniques for Labor Analgesia

Neuraxial techniques represent the most effective form of labor analgesia, and they achieve the highest rates of maternal satisfaction (Declercq et al., 2007). The patient remains awake and alert without sedative side effects, maternal catecholamine concentrations are reduced, hyperventilation is avoided, cooperation and capacity to participate actively during labor are facilitated, and predictable analgesia can be achieved, superior to the analgesia provided by all other techniques.

Epidural Analgesia

Epidural labor analgesia is a catheter-based technique that provides continuous analgesia during labor through the administration of medication into the epidural space. A catheter is inserted through a specialized needle (Fig. 16.2) that is directed between vertebral spinous processes in the back (typically in the lower lumbar segments, L3 to L5). The needle traverses the skin and subcutaneous tissues, supraspinous ligament, interspinous ligament, and the ligamentum flavum and is advanced into the epidural space (Fig. 16.3). The tip of the needle does not penetrate the dura, which forms the boundary between the intrathecal or subarachnoid space and the epidural space. To locate the epidural space, a tactile technique called “loss of resistance” is used. The tactile resistance noted with pressure on the plunger of an air-filled or saline-filled syringe dramatically decreases as the tip of the needle is advanced through the ligamentum flavum (dense resistance) into the epidural space (no resistance). The epidural space has an average depth of approximately 5 cm from the skin. Once the needle is properly positioned, a catheter is inserted through the needle, and the needle is removed. The catheter is secured and analgesia is achieved by administration of local anesthetics, opioids, or both (see [Neuraxial Local Anesthetics](#) and [Neuraxial Opioids](#) sections above) and maintained throughout the course of labor and delivery. The catheter

can also be used for administration of operative anesthesia (cesarean delivery) and postoperative analgesia, when necessary.

After catheter placement, a “test dose” of lidocaine (e.g., 45 mg) and epinephrine (e.g., 15 μg) is administered. If the catheter is inadvertently placed into an epidural vein, the epinephrine causes transient maternal tachycardia and the lidocaine can cause maternal tinnitus and metallic taste. If the catheter is inadvertently positioned

• **Fig. 16.3** Schematic Diagram of Lumbosacral Anatomy Showing Needle Placement for Subarachnoid and Lumbar Epidural Blocks. (From Rosen MA, Hughes SC, Levinson G. Regional anesthesia for labor and delivery. In: Hughes SC, Levinson G, Rosen MA (eds). *Shnider and Levinson's Anesthesia for Obstetrics*. 4th ed. Baltimore: Lippincott Williams & Wilkins; 2002:123-148.)

into the subarachnoid space, the small dose of lidocaine results in the rapid onset of profound maternal analgesia and significant lower extremity weakness. By test-dosing the catheter, possible disastrous complications such as total spinal anesthesia or maternal cardiovascular collapse are significantly minimized.

Epidural medications can be administered in bolus doses or by continuous infusion. Patient-controlled epidural anesthesia (PCEA) is a delivery technique allowing the patient to self-administer small boluses of epidural analgesics with or without a background infusion. Studies comparing PCEA with continuous infusion technique have found decreased local anesthetic requirements, less anesthesia provider intervention, equivalent or improved patient satisfaction, equivalent or decreased motor blockade, and no significant differences in effects on the fetus or neonate (Practice Guidelines for Obstetric Anesthesia, 2016). Using PCEA delivery with a background infusion compared with PCEA alone further improves labor analgesia, reduces the need for clinician boluses, and does not increase maternal or neonatal adverse effects (Heesen et al., 2015).

More recently, programmed intermittent epidural bolus (PIEB) delivery provides automated fixed epidural boluses at scheduled intervals. Similar to continuous infusions, PIEB can be used alone or with a PCEA dosing technique. Recent studies suggest that PIEB slightly reduces local anesthetic usage, improves maternal satisfaction, and decreases the need for rescue boluses when compared with a continuous infusion technique (George et al., 2013; McKenzie et al., 2016).

Dilute solutions of bupivacaine or ropivacaine are typically chosen for epidural labor analgesia, while more potent concentrations of lidocaine or chloroprocaine are often administered for cesarean delivery. As an example of the difference in concentrations, bupivacaine solutions of 0.1% or less are typically used for labor analgesia, while 0.5% bupivacaine would be needed to produce adequate surgical anesthesia for a cesarean delivery. Dilute solutions of local anesthetics minimize the motor blockade and preserve the perception of pelvic pressure with descent of the fetus during labor. Most practitioners routinely use low concentrations of local anesthetics with coadministration of an opioid (e.g., 2 µg/mL fentanyl) for its synergistic effect.

Effects on the Progress of Labor and Rate of Operative Delivery

The use of epidural analgesia has been associated with a prolonged second stage of labor and increased rates of assisted and cesarean delivery. A 2011 systematic review of the literature found that neuraxial analgesia is associated with a 20-minute longer mean duration of the second stage and an increased rate of instrumented vaginal delivery, when compared with the use of systemic opioids for labor analgesia (RR 1.42, 95% CI 1.28–1.57, 23 trials, 7935 women) (Anim-Somuah et al., 2011). This increase in the duration of the second stage is not harmful to the mother or infant and does not dictate intervention with the presence of a reassuring fetal status and ongoing labor progress (ACOG, 2003). The use of epidural analgesia has no effect on the rate of cesarean delivery (Anim-Somuah et al., 2011). Although it was previously believed that placement of an epidural early in labor (<4 cm dilation) increased cesarean delivery rates, randomized controlled clinical trials comparing women receiving either systemic opioids or neuraxial analgesia in early labor (both spontaneous and induced), demonstrated no difference in rates of cesarean delivery (Wong et al., 2005; Sng et al., 2014). Consequently, both the ACOG and the American Society of Anesthesiologists guidelines recommend

that maternal request is sufficient justification for epidural analgesia, and should not depend on an arbitrary amount of cervical dilation (ACOG, 2006; Practice Guidelines for Obstetric Anesthesia, 2016).

Spinal Analgesia

In parturients without epidural analgesia, spinal analgesia can be administered in the second stage of labor near the time of anticipated delivery. A small dose of a local anesthetic, opioid, or both is injected into the subarachnoid space. This dose of local anesthetic is far less than that used for spinal anesthesia for cesarean delivery, and it has minimal effects on motor nerve function. Compared with epidural analgesia, it has the benefits of a more rapid onset, a lower failure rate, and is technically easier and quicker to perform. It has the significant disadvantage of a finite effective duration (approximately 90 minutes), but can be extremely useful for certain circumstances such as forceps-assisted delivery for a woman without epidural analgesia.

Combined Spinal–Epidural Analgesia

CSE labor analgesia is a variation of neuraxial analgesia that combines the lumbar epidural technique and spinal analgesia, using an intrathecal dose to initiate analgesia. After placement of the epidural needle, but before insertion of the epidural catheter, a spinal needle is passed through the indwelling epidural needle (see Fig. 16.2), puncturing the dura, and a small dose of local anesthetic or opioid is administered. Segmental analgesia results more rapidly than with epidural administration of local anesthetics. In a systematic review comparing CSE with epidural labor analgesia, CSE analgesia had a faster onset of effective analgesia (especially in spread to sacral roots), but was associated with more pruritus (Simmons et al., 2012). No differences were seen for mode of delivery, maternal hypotension, postdural puncture headache rate, or need for blood patch.

Contraindications and Complications of Neuraxial Techniques

Certain conditions contraindicate neuraxial procedures: these include patient refusal, infection at the needle insertion site, significant coagulopathy, hypovolemic shock, increased intracranial pressure from mass lesion, and inadequate provider expertise. Other conditions such as systemic infection, neurologic disease, and mild coagulopathies should be evaluated on a case-by-case basis. Human immunodeficiency virus infection is not a contraindication to regional technique in the pregnant patient (Hughes et al., 1995).

Rare, but life-threatening, complications can result from administration of regional anesthesia. Current rates of injury secondary to epidural catheter placement include epidural abscess/meningitis (1:63,000), epidural hematoma (1:250,000), and serious neurologic injury (1:36,000) (D'Angelo et al., 2014). Other serious complications are from accidental IV or intrathecal injections of local anesthetics. An unintended bolus of IV local anesthetic causes dose-dependent consequences ranging from minor side effects (e.g., tinnitus, perioral tingling, mild blood pressure and heart rate changes) to major complications (e.g., seizures, loss of consciousness, severe arrhythmias, cardiovascular collapse). The severity depends on the dose, type of local anesthetic, and preexisting condition of the parturient. Measures that minimize the likelihood of accidental intravascular injection include careful aspiration of the catheter before injection, test dosing, and incremental administration of therapeutic doses.

A “high spinal” (or total spinal) can result from an unrecognized epidural catheter placed subdural, migration of the catheter during its use, or an overdose of local anesthetic in the epidural space (i.e., high epidural). Both high spinals and high epidurals can result in severe maternal hypotension, bradycardia, loss of consciousness, and blockade of the motor nerves to the respiratory muscles. A recently published repository of serious complications in over 250,000 obstetric anesthetics noted high neuraxial block (1:4300), respiratory arrest (1:10,000), and anesthesia-related cardiac arrest (1:128,000) (D’Angelo et al., 2014).

Treatment of complications resulting from both intravascular injection and high spinal is directed at restoring maternal and fetal oxygenation, ventilation, and circulation. Intubation, vasopressors, fluids, and advanced cardiac life support algorithms are often required. In any situation of maternal cardiac arrest with unsuccessful resuscitation, the fetus should be delivered by surgical hysterotomy if the mother is not resuscitated within 4 minutes of the arrest. This guideline for emergent cesarean delivery increases the chances of survival for both the mother and neonate (Katz et al., 1986; Jeejeebhoy et al., 2015).

A variety of less severe complications such as inadequate analgesia, headache, or hypotension can occur with neuraxial blockade. The retrospective rates of inadequate epidural analgesia or inadequate CSE analgesia requiring catheter replacement were 7% and 3%, respectively, at a US academic center (Pan et al., 2004). The rate of accidental dural puncture during epidural catheter placement is 1.5%, and approximately half of these will result in a severe headache (Choi et al., 2003). These post-dural puncture headaches are typically managed with analgesics or a blood patch if necessary. Hypotension (decrease in systolic blood pressure greater than 20%) secondary to sympathetic blockade is the most common complication of neuraxial blockade for labor analgesia, with rates of approximately 14% (Simmons et al., 2012). Prophylactic measures include left uterine displacement and hydration. Although standards for timing, amount, and hydration fluid remain controversial, dehydration should be avoided. There is no significant difference in rates of hypotension following spinal anesthesia if a preload or coload of IV crystalloid or colloid is administered (Banerjee et al., 2010; Tawfik et al., 2014; Practice Guidelines for Obstetric Anesthesia, 2016). Hypotension treatment consists of further uterine displacement, IV fluids, and vasopressor administration. Small boluses of either phenylephrine or ephedrine can be used to treat hypotension. Although ephedrine (primarily β -adrenergic) was historically used, phenylephrine (primarily α -adrenergic) is associated with less fetal acidosis (Ngan Kee et al., 2009; Butwick et al., 2015). If treated promptly, maternal hypotension does not lead to fetal depression or neonatal morbidity.

A rise in core maternal body temperature and fever is associated with labor epidural analgesia. Although it was originally believed that all women who had epidural analgesia gradually increased their core temperature, more current studies suggest that only about 20% of women who receive epidural labor analgesia develop a fever and the remaining 80% have no increase in core body temperature (Arendt and Segal, 2013). Although the etiology of the maternal temperature rise remains uncertain, an association with noninfectious inflammation mediated by proinflammatory cytokines is supported most consistently in the literature. It is not associated with a change in white blood cell count or with an infectious process, and treatment is not necessary (Arendt and Segal, 2013). In addition, the fever associated with epidural labor analgesia does not increase the incidence of neonatal sepsis and need not affect neonatal septic work-up.

Other potential side effects from neuraxial blockade during labor include pruritus, nausea, shivering, urinary retention, motor weakness, and a prolonged block.

Paracervical Block

A paracervical block is infrequently used to provide pain relief during the first stage of labor. Analgesia is not as profound as with epidural or spinal regional block, and the duration of analgesia is short (45–60 minutes). The technique consists of submucosal administration of local anesthetics immediately lateral and posterior to the uterocervical junction, which blocks transmission of pain impulses at the paracervical ganglion. Complications from systemic absorption or transfer of local anesthetic can occur and there is a rare occurrence of direct fetal trauma or injection. A paracervical block is associated with a 15% rate of fetal bradycardia based on a metaanalysis of studies (Rosen, 2002b). The bradycardia is usually limited to less than 15 minutes, and treatment is supportive.

Pudendal Block

A pudendal block is infrequently used to provide pain relief during the second stage of labor at the time of delivery. In most centers this technique is used when epidural or spinal techniques are unavailable. A sheathed needle is guided to the vaginal mucosa and sacrospinous ligament just medial and posterior to the ischial spine. Injection of local anesthetic blocks sensation of the lower vagina and perineum. Although the technique can provide analgesia for vaginal delivery or uncomplicated instrumental delivery, the rate of failure is high (Nikpoor and Bain, 2013). Additional complications include systemic local anesthetic toxicity, ischiorectal or vaginal hematoma, and, rarely, fetal injection of local anesthetic.

Anesthesia for Cesarean Delivery

In the United States, the vast majority of cesarean deliveries are performed with neuraxial anesthesia. It offers the advantages of less anesthetic exposure to the neonate, has the benefit of an awake mother at the delivery, allows for placement of neuraxial opioids to decrease postoperative pain, and avoids the risks of maternal aspiration and difficult airway associated with general anesthesia. However, the use of general anesthesia is sometimes required if regional anesthesia is contraindicated (e.g., coagulopathy, hemorrhage) or for emergent deliveries (e.g., fetal bradycardia, uterine rupture). Benefits of general anesthesia compared with regional anesthesia include a secure airway, controlled ventilation, rapid and reliable onset, and potential for less hemodynamic instability.

Epidural Anesthesia for Cesarean Delivery

Epidural anesthesia is an excellent choice for surgical anesthesia when an indwelling, functioning labor epidural catheter is in place. Epidural anesthesia provides the ability to titrate the desired level of anesthesia and extend the block time if needed. The volume and concentration of local anesthetic agents used for surgical anesthesia are larger than those used for labor analgesia. Typically the anesthesiologist attempts to provide a dense block from the T4 level to the sacrum. This technique might not completely alleviate the visceral pain and pressure sensation associated with peritoneal manipulation, and adjuvant drugs are occasionally

necessary. Epidural block failure rates for cesarean delivery following use of a labor epidural are known to be greater in the urgent setting compared with elective cases and range between 1.7% and 19.8% (Carvalho, 2012). In some cases conversion to general endotracheal anesthesia may be required. Antiemetics are frequently given to decrease nausea and vomiting associated with the cesarean delivery and hemodynamic effects from the dense neuraxial blockade. Epidural morphine is typically administered near the end of the procedure to decrease postoperative pain for up to 24 hours.

Spinal Anesthesia for Cesarean Delivery

For the patient without an epidural catheter, spinal anesthesia is the most common regional anesthetic technique used for cesarean delivery. The block is technically easier than epidural placement, more rapid in onset, and more reliable in providing surgical anesthesia from the midthoracic level to the sacrum (Riley et al., 1995). The risk of profound hypotension is greater with spinal anesthesia than with epidural anesthesia because the onset of the sympathectomy is more rapid. However, this risk can be nearly eliminated by avoidance of aortocaval compression, prehydration, and appropriate use of vasopressors. Data suggest that spinal anesthesia can be used safely for patients with preeclampsia (Hood and Curry, 1999). A typical spinal anesthetic could consist of hyperbaric bupivacaine with morphine added to decrease postoperative pain. A hyperbaric solution facilitates appropriate local anesthetic spread in the cerebrospinal fluid to a position near T4. The duration of a single-shot spinal anesthetic is variable, but normally provides adequate surgical anesthesia for greater than 90 minutes. In selected circumstances, the use of a CSE technique offers the advantage of a spinal anesthetic, with rapid onset of a dense block and the ability to administer additional local anesthetic through the epidural catheter if the procedure lasts for an extended time.

Local Anesthesia

Although cesarean delivery can be performed with local infiltration, it is accompanied with considerable discomfort to the woman and risks the possibility of local anesthetic overdose. Most obstetricians are not trained to perform the technique. However, local tissue infiltration is useful in rare circumstances, such as acute fetal distress without an available anesthesia provider.

General Anesthesia

Use of general anesthesia for cesarean delivery is typically reserved for situations where neuraxial anesthesia is contraindicated or emergent delivery is needed. Based on data from the period 1997–2002, the RR of general anesthesia is 1.7 times that of neuraxial anesthesia, with two-thirds of the mortality associated with general anesthesia caused by intubation failure or induction problems (Hawkins et al., 2011). Appropriate airway examination, preparation for unanticipated events, and familiarity with techniques and the algorithm for difficult intubation are critical for providing a safe general anesthetic. A current multi-institutional database of adverse obstetric anesthesia events notes that rates of failed intubation are approximately 1:533, although none of the ten failed obstetric intubations in the study resulted in maternal mortality (D'Angelo et al., 2014).

After denitrogenation of the lungs (i.e., preoxygenation), general anesthesia is induced by rapid-sequence administration of an IV

induction agent, followed by a rapidly acting muscle relaxant. The trachea is intubated with a cuffed endotracheal tube, and a surgical incision is made after confirmation of tracheal intubation and adequate ventilation. Anesthesia is maintained by administering inhaled halogenated agents (e.g., sevoflurane), as well as benzodiazepines, opioid analgesics, propofol, nitrous oxide, and additional muscle relaxants if needed. These additional intravenous agents are normally administered after the baby is delivered to avoid placental transfer to the neonate. Before delivery of the baby, the primary anesthetic for the incision and delivery is the IV induction agent, because there is little time for uptake and distribution of the inhaled agents into the mother or fetus (Dwyer et al., 1995). If intubation attempts fail, the cesarean delivery may proceed if the anesthesiologist communicates that it is possible to reliably ventilate the mother's lungs with either a facemask or a laryngeal mask airway (Practice Guidelines for Obstetric Anesthesia, 2016). Halogenated agents are often partially replaced with other anesthetic agents following delivery to decrease the adverse effects on uterine muscular tone (atony).

Induction Agents

Anesthesiologists use a variety of agents to rapidly induce unconsciousness. Among the most common are propofol, etomidate, and ketamine. Each agent represents a different biochemical class, and each has specific advantages and cardiovascular effects.

Propofol action is rapid in onset with an umbilical artery to umbilical vein (UV) ratio of 0.7 (Dailland et al., 1989). Propofol administration has no significant effect on neonatal behavior scores, with typical induction doses of 2.5 mg/kg; however, larger doses (9 mg/kg) are associated with newborn depression (Gregory et al., 1990). Why there is a lack of neonatal effects is unclear, but may be caused by redistribution into maternal vascular-rich tissue beds, first-pass metabolism by the neonatal liver, additional dilution by the fetal circulation, and higher fetal brain water content.

Etomidate also has a quick onset of action because of its high lipid solubility. It rapidly crosses the placenta, and rapid hydrolysis and redistribution results in a relatively short duration of action. Unlike propofol, etomidate has minimal effects on the cardiovascular system, can cause involuntary muscle tremors, has higher rates of nausea and vomiting, and can increase the risk of seizures in patients with decreased thresholds. At typical induction doses (0.3 mg/kg), etomidate administration can cause decreased neonatal cortisol production (<6 hours), but the clinical significance remains uncertain (Crozier et al., 1993).

Ketamine, a structural analogue to phencyclidine, is an analgesic, hypnotic, and amnestic with minimal respiratory depressive effects. In contrast to propofol, sympathomimetic characteristics of ketamine increase arterial pressure, heart rate, and cardiac output through central stimulation of the sympathetic nervous system. Similar to etomidate, it is an appropriate choice for a patient in hemodynamic compromise. No neonatal depression is noted with typical induction doses (Little et al., 1972). Larger doses can increase uterine tone and reduce uterine arterial perfusion. Even in low doses, ketamine has profound analgesic effects.

Nitrous Oxide

Inhaled nitrous oxide is often used as part of maintenance for general anesthesia because of its minimal effects on maternal hemodynamics and uterine tone. Alone, it is insufficient to provide adequate anesthesia for cesarean delivery. It rapidly crosses the placenta with increasing UV to maternal artery ratios of 0.37 in the first 2–9 minutes, increasing to 0.61 at 9–14 minutes (Karasawa

et al., 2003). The effects of nitrous oxide on the neonate are not significant. Additional information about nitrous oxide is found in the section on Analgesic Options for Labor and Vaginal Delivery: *Inhaled Nitrous Oxide*.

Inhaled Halogenated Anesthetics

Isoflurane, sevoflurane, and desflurane are all halogenated hydrocarbons that differ in chemical composition, physical properties, biotransformation, potencies, and rates of uptake and elimination. In clinical use, specialized vaporizers deliver these volatile liquid agents, so that the inhaled concentrations can be carefully titrated by anesthesiologists because of the relatively profound cardiovascular effects and potential for uterine muscle relaxation. These agents are important components of general anesthesia for cesarean delivery, but readily cross the placenta. Placental transfer of inhalation agents is rapid because these are nonionized, highly lipid-soluble substances of low molecular weight, which cross the placenta to the fetus by diffusion along a concentration gradient, much like oxygen and carbon dioxide. The concentrations of these agents in the fetus depend directly on the concentration and duration of anesthetic in the mother. Although general anesthesia is often utilized when emergent cesarean delivery is required, neonatal depression is more likely due to the previously compromised fetus than the impact of anesthesia. A depressed fetus will probably become a depressed neonate. A Cochrane review of 16 studies comparing neuraxial blockade with general anesthesia in otherwise uncomplicated cesarean deliveries found that “no significant difference was seen in terms of neonatal Apgar scores of six or less and of four or less at five minutes and need for neonatal resuscitation” (Afolabi and Lesi, 2012). The authors concluded that there was no evidence to show that neuraxial anesthesia was superior to general anesthesia for neonatal outcome.

Recent experimental animal studies have demonstrated neuronal apoptosis in the developing brain when a variety of agents are administered to induce and maintain general anesthesia (Loepke and Soriano, 2008; Istaphanous and Loepke, 2009). Implications for the fetus and neonate from the extremely brief anesthetic exposures associated with cesarean delivery are currently unknown because of a lack of human studies and difficulties extrapolating animal study methodology to humans.

The “induction-to-delivery” interval is not as important in neonatal outcome as the uterine “incision-to-delivery” interval, during which uterine blood flow can be compromised and fetal asphyxia can occur. A long induction-to-delivery time can result in a neonate who is lightly anesthetized but should not be associated with causing asphyxia. If inhaled anesthetics are administered to the mother for a prolonged period, neonatal anesthesia, evidenced by flaccidity, cardiorespiratory depression, and decreased tone, can be anticipated (Moya, 1966). In such cases, the infant would be lightly anesthetized and should easily respond to basic, supportive treatment measures focused on effective ventilation; cardiopulmonary resuscitation should not be necessary. Ventilation will allow elimination of the inhalation anesthetic by the infant’s lungs since the two factors that govern recovery from inhaled anesthesia are the rate of delivery of anesthetic back to the lungs from body tissues (by cardiac output) and the rate of fall of the alveolar anesthetic concentration through exhalation (by ventilation). Rapid improvement of the infant should be expected; otherwise, a search for other causes of depression is imperative. For these reasons, it is critical that clinicians experienced with neonatal ventilation be present at cesarean deliveries during which the mother receives

general anesthesia and the time from skin incision to delivery is expected to be prolonged (e.g., known percreta, large fibroids), or maternal condition necessitates an atypical induction and maintenance of anesthesia. A discussion of the operative and anesthetic plan by the neonatologist, obstetrician, and anesthesiologist is crucial for optimizing the outcome of neonates in these situations.

Neuromuscular Blocking Agents

Succinylcholine remains the skeletal muscle relaxant of choice for obstetric anesthesia, because of its rapid onset and short duration of action. In appropriate doses (1–1.5 mg/kg), intubating conditions are achieved within 45 seconds. Because it is highly ionized and poorly lipid soluble, only small amounts cross the placenta. Side effects include increased maternal potassium levels and myalgias, and succinylcholine is a known trigger agent for malignant hyperthermia in susceptible individuals. This depolarizing neuromuscular blocking agent is normally hydrolyzed in maternal plasma by pseudocholinesterase and usually does not interfere with fetal neuromuscular activity. Although pseudocholinesterase activity is decreased in pregnancy, neuromuscular blockade by succinylcholine is not significantly prolonged. If large doses are given (2–3 mg/kg), it results in detectable levels in umbilical cord blood, but extreme doses (10 mg/kg) are needed for the transfer to result in neonatal neuromuscular blockade.

Rocuronium is a rapid-acting, nondepolarizing neuromuscular blocker that is an acceptable alternative to succinylcholine. It provides adequate intubating conditions in approximately 60–90 seconds in appropriate doses. Unlike succinylcholine, it has a much longer duration of action, decreasing maternal safety in the event the anesthesiologist is unable to intubate or ventilate the patient. It has the benefit of not being a triggering agent of malignant hyperthermia or elevating serum potassium levels.

During the operation, nondepolarizing neuromuscular blocking agents can be titrated to improve operating conditions. Under normal circumstances, the poorly lipid-soluble, highly ionized, nondepolarizing neuromuscular blockers (i.e., rocuronium, vecuronium, cisatracurium, pancuronium) do not cross the placenta in amounts significant enough to cause neonatal muscle weakness (Kivalo and Saarikoski, 1972). This placental impermeability is only relative, however, and neonatal neuromuscular blockade can occur when large doses are given (Older and Harris, 1968).

The diagnosis of neonatal depression secondary to neuromuscular blockade can be made on the basis of the maternal history (e.g., prolonged administration of neuromuscular blockers, history of atypical pseudocholinesterase), the response of the mother to neuromuscular blocking drugs, and the physical examination of the newborn. The paralyzed neonate has normal cardiovascular function and good color, but lacks spontaneous ventilatory movements, has muscle flaccidity, and shows no reflex responses. The anesthesiologist can place a nerve stimulator on the neonate and demonstrate the classic signs of neuromuscular blockade. Treatment consists of ventilatory support for up to 48 hours until the neonate excretes the drug. Reversal of nondepolarizing relaxants with cholinesterase inhibitors may be attempted (e.g., neostigmine, 0.06 mg/kg), but adequate ventilatory support is the mainstay of treatment. Concomitant administration of an anticholinergic (e.g., atropine, glycopyrrolate) is normally necessary to prevent severe bradycardia from muscarinic side effects of the increased acetylcholine.

Summary

This chapter serves as a general overview of the changes in maternal physiology during pregnancy and briefly discusses options and techniques for both labor analgesia and anesthesia for cesarean delivery. Its purpose is to allow the pediatrician and neonatologist a better understanding of the decisions and concerns of the anesthesiologist and the implications of his or her interventions.

The Human Genome and Neonatal Care

C. MICHAEL COTTON AND JEFFREY C. MURRAY

KEY POINTS

- In the 50 years since the identification of the double helix, and the 15 years since the publication of the almost complete sequence of the human genome, the amount of information about the human genome, its construction, and how it is regulated has exploded.
- Thousands of individuals have had their entire genomes or exomes sequenced and shared, along with corresponding phenotype information. This comprehensive genome, exome, and linked phenotype information enhances our ability to identify genetic links with previously unexplained structural and functional disorders among newborns.
- The rapidity of adoption of new technology and informatics is challenging clinicians to keep up with the rapidly expanding understanding of the genome and how it impacts patients and their families.

Within 50 years of the discovery of the double helix structure of DNA by Watson and Crick, the Human Genome Project achieved the major milestone of identifying an almost complete sequence of the approximately 3 billion nucleotides contained in the human haploid genome (International Human Genome Consortium, 2001; Venter et al., 2001). Since the publication of these single consensus genomes, advances in sequencing technology have enabled the reporting of in excess of 100,000 complete genomes and the characterization of millions of genetic variants in millions of individuals. These developments have advanced our understanding of gene function and regulation and have led to the direct consumer use of genetics and the discovery of the genetic contributors to thousands of common and rare diseases.

Linking genetic variations to disease is a key step to advancing understanding of pathophysiology and human development that will lead to better treatment and management strategies. The potential impact of personal genotype–phenotype information, now widely characterized as one component of precision medicine, is as worthy of concerted collaborative efforts and study as are the exciting advances in knowledge of pathophysiologic and developmental biology aspects of disease (Collins and Varmus,

2015). Newborn medicine has not seen the degree of inclusion of the genome as has cancer and other common adult medicine disorders such as type 2 diabetes and macular degeneration. However, genetic sequencing and informatics analysis technologies and approaches are now being widely used in the diagnosis of newborn birth defects and metabolic disorders, and while it may someday be applied to newborn screening directly, a host of technical and ethical issues will first need resolution (Botkin et al., 2015; Botkin and Rothwell, 2016; Lantos, 2016).

This chapter reviews key concepts about the human genome, particularly its components and structure and certain types of variations. We review the evolving use of genome-focused tools by clinicians and researchers trying to identify novel causative genes for fetuses and neonates with suspected monogenic conditions. We also discuss evolving information and use of genomic testing to identify associations between genetic variations and the complex disorders associated with preterm birth, focusing on intraventricular hemorrhage (IVH) and bronchopulmonary dysplasia (BPD). Finally, we discuss how the massive amount of genomic information emerging from thousands of accumulating sequenced individuals challenges us to question how best to use this information to provide better prenatal, perinatal, and neonatal clinical care.

History of Mapping and Sharing the Genome

The Human Genome Project has been an international effort from its beginnings and had critical predecessors in the human gene mapping (HGM) meetings focused on identifying the chromosomal location of normal and disease-causing genetic variants. The community established by the HGM meetings provided an infrastructure that enabled the more comprehensive sequence-based maps to be developed in the wake of the HGM meetings (Watson and Cook-Deegan, 1991). The international effort continues, with some countries conducting population-based studies applying whole genome or exome sequencing to tens of thousands of individuals (Manolio et al., 2015). By participating in collaborative efforts, clinicians and researchers have now published studies of comprehensive views of genetic variation for hundreds of thousands of individuals with type 2 diabetes, breast cancer, or normal traits

such as height or birth weight. These collaborative international efforts have created the framework for one of the greatest successes of the Human Genome Project—that is, information generated relevant to the human DNA sequence and its variation held in public trust and with open access to the scientific community through accessible databases and analytic platforms that now number in the dozens (NCBI Resource Coordinators, 2016).

One major hub for clinicians that contains both clinical and scientific descriptors of genetic findings that is searchable by disease, phenotype, or genetic variant is the website Online Mendelian Inheritance in Man (OMIM)—a comprehensive catalogue, updated daily, of now more 15,000 genes and diseases with some degree of association, including the ever-growing total of more than 4000 validated single gene disorders. The online version, www.ncbi.nlm.nih.gov/omim/, a compendium of human genes and phenotypes, also provides links to multiple other online resources that provide information about genetic variants, including their associations with disease, genetic conservation across species, the differences in variant prevalence between populations of different ancestries, predicted variations in protein structures relative to genetic variations, proteins, and classification of genes in thousands of different biological pathways (<http://omim.org/help/external>). The Clinical Sequencing Exploratory Research Consortium, funded by the National Human Genome Research Institute and the National Cancer Institute, is among the newest collaborative efforts accumulating whole genome and exome sequences and studying their role within the practice of medicine. The consortium is exploring analytic and clinical validity and utility, as well as the ethical, legal, and social implications of sequencing via multidisciplinary approaches (Green et al., 2016).

Defining the Genome and Genomics

While genetics as a discipline is focused on the study of single genes and their effects, genomics is defined as the comprehensive study of the functions and interactions of all the genes in the genome. The genes of eukaryotic organisms are divided into exons and introns. Exons are regions of DNA that are “expressed” or translated into protein and can include regulatory signals for how much of that gene product is made and in what tissue. Introns are intervening regions that are not translated into protein. The “exome” is the collective term for all of the exons. Despite their apparent importance and influence as being the “source code” for the proteins that allow us to function, exons account for less than 2% of the DNA in the entire genome. Regions outside of the formal coding exons are increasingly recognized for playing critical roles in how and when the genes themselves are expressed and functioning. The Human Genome Project quantified the total number of base pairs (bps; approximately 3 billion), and defined genes to approximately 30,000, and provided more information about how genomic DNA might be classified. The very definition of what a “gene” is changes as we learn more about distant regulatory elements, DNA modifications, chromatin structure, gene–gene interactions, alternative splicing and exon skipping, post-translational modification, and a host of other factors that determine what a gene does and is (Guttmacher and Collins, 2002; US Department of Energy, 2013).

In the years since the description of the primary human sequence, a deeper understanding of the nature of the DNA and its sequence and its regulation, and definitions of exons and introns, has developed. Interestingly, we have learned that approximately 8% of the intronic base sequences are the products of human endogenous

retroviruses. The segments are DNA-based copies of their own ribonucleic acid (RNA) genetic material inserted over millennia in the human genome (Wildschutte et al., 2016). Even before the sequencing of the complete human genome, we knew that there were regulatory regions of the genome close to exons, sometimes called *promotor regions*. These are sites where transcription factors can bind to “turn on” or “turn off” a gene’s expression. The regulatory region is usually a different set of bps than the actual transcription start site where transcription of messenger RNA (mRNA) is initiated (Geer and Messersmith, 2002). Understanding how noncoding, nonregulatory region sequences play a role in human health and disease will be an important area of study for decades to come.

As our understanding of the genome has expanded, we have learned that many more RNAs and proteins can be made from the DNA that underlies what we previously thought were single genes. While approximately 30,000 physically discrete genes are known, the principle of alternative splicing—i.e., mRNA composed of different exons from the same gene—increases the estimate of the number of proteins possible from 30,000 to well over 100,000. The basic principle is that mRNA can be transcribed from different exons within the same gene to make different proteins. One important example is in the developing neuronal system, in which over 90% of multi-exon genes are alternatively spliced throughout development (Wang et al., 2008; Mitchell, 2011; Norris and Calarco, 2012; Shi et al., 2012; Gazina et al., 2015).

Mitochondrial DNA

Mitochondria are the energy-producing organelles present in thousands of copies within each cell. Each mitochondrion has its own genome, distinct from the nuclear genome, and is thought to have arisen from incorporation of bacterial DNA by a eukaryotic cell. Although the mitochondrial genome is approximately 16,500 bps in length, there is a wide range of disorders, some lethal, associated with variation in the mitochondrial sequence. In addition, because mitochondria reside in the cytoplasm and are not found in sperm, they have a unique pattern of maternal-only inheritance, in which mothers pass their mitochondria to all of their offspring, with their daughters in turn passing that on to subsequent generations and with no passing of mitochondrial DNA from males to their children. The knowledge that variants in mitochondrial DNA can cause disease, plus the progress made in techniques and technology for molecular and cellular manipulation, has led to embryonic mitochondrial transplantation, where “healthy” mitochondria are transplanted into the cytoplasm of an early-stage embryo identified to have a lethal mitochondrial variant (Richardson et al., 2015; Committee on the Ethical and Social Policy, 2016).

Types of Variation in the Human Genome

Single Nucleotide Polymorphisms

Single nucleotide polymorphisms (SNPs) were the first commonly characterized contributors to human genetic variation in the molecular age. Prior to that, only visible chromosomal variants and amino acid variants found in proteins comprised the known genetic variations in humans, and these were limited in number and were prohibitively expensive to characterize at a population level. SNPs are specific nucleotide sites in the human genome where it is possible to have two (or even three or four) different nucleotides at a specific position on a chromosome. For example, there might be either a Thymine or a Guanine at a specific site. These sites in the genome

where variations occur are common, with up to 1% of the 3 billion bps of the human DNA sequence being potentially variable between any two individuals, resulting in tens of millions of SNPs across the genome. Most variation is found across all human populations, although some variants appear to be highly population-specific or ancestry-specific. Chip-based DNA genotyping allows the genotyping assays of greater than 1 million SNPs simultaneously on one individual at a cost approximating US\$100. Examples of these genome-wide studies of diseases of premature neonates are described later in the chapter. Known SNPs are catalogued in the online public-domain resource the Single Nucleotide Polymorphism database (dbSNP: <http://www.ncbi.nlm.nih.gov/snp>). Most SNPs appear to not be disease-causing themselves, although they may lie adjacent to DNA changes that do contribute to disease predisposition and can be detected using the phenomena of linkage disequilibrium (Christensen and Murray, 2007).

Copy Number Variants

A relatively recent discovery in human genetic variation has been the importance of copy number variants (CNVs) as contributors to human inherited disorders. Although both small and large deletion and duplication events of the human DNA sequence have been known since the 1970s, based on cytogenetic banding, only recently has the widespread role that these play in disease been recognized. CNVs can range in size from a few nucleotides to thousands, or occasionally hundreds of thousands, or millions of bps in length, resulting in the possibility that two healthy people could have complete genomes with total numbers of bps that differed by millions (Redon et al., 2006). These variations may contain one or multiple genes that can exist in two, three, or more copies arrayed in tandem at particular chromosomal positions. When these tandem arrays of largely identical sequences align themselves during meiosis, there is occasionally a misalignment that can result in the deletion or duplication of one or more of the copies. This event in turn can create a range of the number of copies present from zero to many (Zhang et al., 2009). When functional genes or functional regulatory elements are contained within the copied or deleted element, the amount of gene product made may be increased or decreased from a reference level. Early examples in which CNVs contributed to disease include the DiGeorge syndrome 22q deletion and deletions associated with spinal muscular atrophy and Charcot-Marie-Tooth disease. New microdeletion syndromes are being characterized with great precision using array-based DNA analysis that has rapidly replaced the traditional karyotype as the first line of chromosomal analysis. Other rearrangements leading to congenital anomalies, developmental delay, or both, include the 15q11-q13 defects seen in Prader-Willi syndrome and Angelman syndrome. The origin of the rearrangement, either the maternal or paternal chromosome with the CNV, determines which of the two phenotypes emerge (Prader-Willi if the paternal-derived chromosome has the variant, and Angelman if the deletion is in the inherited maternal chromosome) (Morrow, 2010). Finally, in areas such as autism, it is clear that these microdeletion or duplication events are a contributing explanation for the sometimes sporadic, as well as familial nature, of these disorders. Their contribution to human genetic disease is now suggested to be in excess of 10% of all variant-contributed disease. Despite their importance, many technical and clinical issues related to their identification and meaning remain unresolved (Ali-Khan et al., 2009). Additionally, their widespread presence creates clinical challenges in determining whether they are causal or merely coincidental in clinical cases (Martin et al., 2015).

Chromosomal microarrays, which include assessments of insertions, duplications, and deletions across the entire genome as well as some allelic variants strongly associated with disease, have become the most commonly used clinical test to identify CNVs (Watson et al., 2014).

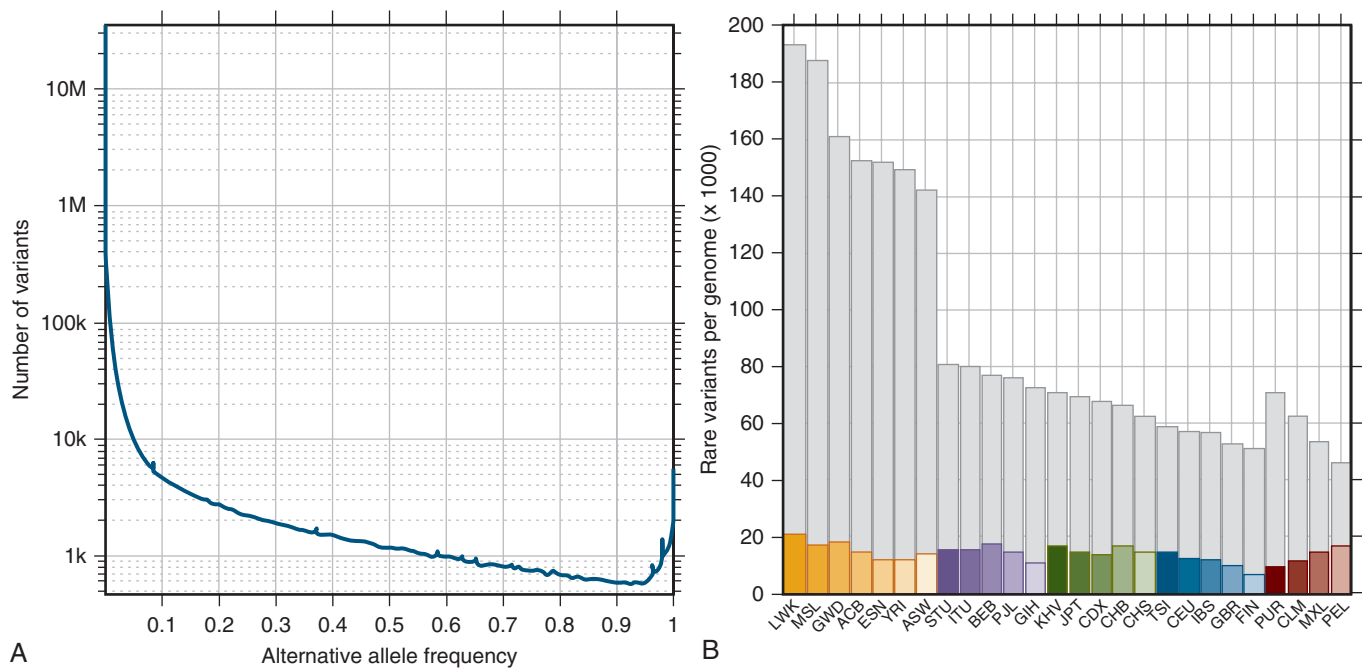

Current Variant Counts

In the years since completion of the human genome map and with progress being made with sequencing, the number of identified variants in the map has exploded. As recently as 2015, in results from whole genome sequencing of over 2500 individuals from 26 populations of varying ancestry, over 88 million variants have been identified. Almost 85 million are SNPs, 3.6 million are insertion/deletions, and 60,000 are structural variants. Interestingly, the vast majority of SNPs occur rarely. Over 60% of the autosomal variants identified across all individuals had population frequencies of less than 0.5%. Many of these were observed to be much more common in at least one specific geographically defined ancestry group. A “typical” single individual is likely to have 4–5 million variants, with most being SNPs and short insertion/deletions, with only 1%–5% of these (40,000–200,000) being “rare variants” with a frequency of less than 0.5% in the population. Of these, most are inherited from parents, and 50–100 are *de novo* (Veltman and Brunner, 2012). Most of these variants do not appear to be linked with disease, either by being predicted as protein-truncating variants, or peptide-sequence altering variants, or variants overlapping known promotor regions, or other functional genomic regions, but if they do fall into one of these categories, they can lead to disordered development or disease (The 1000 Genomes Project Consortium, 2015) (Fig. 17.1).

Regulation of Gene Expression

In addition to variations in genomic DNA, gene expression can also be modified by molecular structures outside of genomic DNA. The key components of these epigenetic modifiers are direct biochemical modifications to genomic nucleotides, the proteins that form the core around which DNA wraps (histones), and short strands of noncoding RNA such as microRNA (miRNA; Bird, 2007). Methylation of DNA nucleotides can either interfere with or block transcription-factor binding to DNA or can recruit compounds that bind only to methylated DNA and suppress transcription (Robertson and Wolffe, 2000; Bird, 2007). During embryogenesis, methylation depends on the supply and enzymatic transfer of methyl groups to genomic DNA, which requires energy, suggesting links between methylation and nutrition. In animal models, variation in methylation has been observed with changes in the environment, diet, and the presence or absence of a nurturing environment (Weaver et al., 2004; Desai et al., 2015). Histones can also be methylated and acetylated, and differential lysine methylation or acetylation leads to repression or activation of gene transcription (Desai et al., 2015). Modification in methylation of histones has been associated with obesity and type 2 diabetes (Jufvas et al., 2013). The classic example of epigenetic modification in humans comes from studies of 60-year-old survivors prenatally exposed to starvation during the Dutch Hunger Winter (1944–1945) and their siblings born in less-stressed years. Epigenetic modifications were noted in methylation of whole blood *IGF2* gene, two obesity-related non-imprinted genes (*TNF*, *leptin*) as compared with their unexposed, same-sex siblings (Heijmans et al., 2008).

MiRNAs are unique short strands (18–25 nucleotides) of transcribed, single-strand RNA that bind to mRNA and inhibit

• **Fig. 17.1** Figure of Variant Counts: Where's the Variation? Variant counts. (A) The number of variants within the phase 3 sample as a function of alternative allele frequency. (B) The average number of detected variants per genome with whole-sample allele frequencies of less than 0.5% (gray bars), with the average number of singletons indicated by colors. (From The 1000 Genomes Project Consortium, Auton A, Brooks LD, et al. A global reference for human genetic variation. *Nature*. 2015; 526: 68–74.)

efficient translation of the targeted, complementary mRNA into protein. They have been estimated to comprise 1% of all the genes in humans as well as other animals. Over 1900 have been characterized and listed on mirbase.org, <http://mirbase.org/> (Kozomara and Griffiths-Jones, 2011; Tétreault and De Guire, 2013). One miRNA can suppress hundreds of different mRNAs and, overall, may impact transcription of up to one-third of the genes in the human genome (De Guire et al., 2013). They have been described among all plants and animals, and even some unicellular organisms, with highly conserved structures (Lewis et al., 2005; Mendell, 2008; Stefani and Slack, 2008). Interestingly, they can be extruded from cells and travel freely in blood and are found in multiple biologic fluids (Cortez et al., 2011; Tétreault and De Guire, 2013). Early work characterized their importance in tumorigenesis, through mechanisms such as inhibition of tumor suppression pathway genes or apoptosis inhibition, or, as in the originally described association between miRNA with B-cell leukemia, deletion of the miRNA sequence allowed overexpression of an antiapoptotic factor that led to B-cell leukemia (Cimmino et al., 2005; Petrocca et al., 2008). They have been implicated as important in neuronal, muscle, lung, heart (size, structure, and conductance), and immune cell development, as knock-out or mutations of specific miRNAs lead to birth defects, cardiac arrhythmias, severe lung hypoplasia, and ventricular septal defects (Stefani and Slack, 2008; Ventura et al., 2008; Tétreault and De Guire, 2013).

Connecting Genes to Diseases

Identification of Disease-Related Genes

One hundred and one years prior to the sequencing of the human genome, Archibald Garrod noted that alkaptonuria seemed to occur at high prevalence among children born to parents who

were first cousins. From this, he hypothesized that this dark urine effect was probably a disorder of metabolism inherited according to Mendel's laws of heredity, the first disorder in humans attributed to what would become genetics. He also noted that the chemical basis for darkening the urine could be a sign of human biologic diversity, one that could be harmless, but other such inherited traits might be manifest as lethal disease. He coined the term *inborn errors of metabolism* to describe diseases caused by errors and variations in chemical pathways (Garrod, 1902; Scriver, 1996). Over the next 100+ years, particular facts about DNA and its impact on human development and disease have come to light, including, at approximately the midpoint between Garrod and the Human Genome Project, the identification of the double helix as the structure that allows for transcription and translation (Watson and Crick, 1953).

Clinicians caring for neonates in the intensive care nursery often hypothesize that genetics or the interaction of the individual neonate's genome and environment must contribute to structural anomalies, metabolic derangements, and the common, complex disease phenotypes noted among newborns and prematurely born neonates. Currently we estimate that 5%–10% of newborns have congenital or chromosomal disorders. For decades, 20% of infant deaths in the United States have been attributed to chromosomal and congenital anomalies. Of these, only a small minority will have an identified syndrome or identified genetic cause (Sowards, 1999; Mathews and MacDorman, 2007; Carmichael, 2014). In addition to the deaths readily attributable to congenital defects or chromosomal abnormalities, deaths attributed to sudden infant death syndrome are more and more often associated with genetic variations identified through sequencing and subsequent testing of variants in model systems, potentially adding substantially to the number of deaths attributable to genetic variation (Van Norstrand and Ackerman, 2010). In addition to mortality risk,

newborns with complex congenital anomalies and chromosomal disorders who survive beyond the first days and weeks are vastly overrepresented among hospitalizations in pediatric wards and intensive care units. These children are hospitalized more often and have hospitalizations that are longer and more expensive than children without underlying chromosomal anomalies or congenital defects (McCandless et al., 2004; Colvin and Bower, 2009; Jama-Alol et al., 2014; Razzaghi et al., 2015). As clinicians begin to understand the complex interactions between the entire genome and the environment and work to optimize use of the sequencing tools, informatics, and genomic analysis strategies that are emerging, these estimates may increase. As more genetic variants are linked with disease, our hope is that our ability to provide care based on better understanding of the pathophysiology of the disease and susceptibility to complications, such as respiratory infections, that arise from awareness of the genetic variations at the heart of the problem will guide preventive and treatment strategies that will improve outcomes (Beaulieu et al., 2012).

One of the primary benefits of the reference human DNA sequence is our ability to move quickly from finding the location of a gene on a chromosome to identifying the specifics of that gene and the disease-causing mutations. Gene mapping approaches to human gene identification have been in use since the late 1970s, and the first successes were the identification of single-gene disorders, sometimes termed *monogenic* or *Mendelian* because their inheritance patterns follow the traditional modes of autosomal dominant, autosomal recessive, and sex linked.

There are three primary methodologies for gene identification (Altshuler et al., 2008). The first involves linkage studies using large families with genetic disorders or many small families with the same disorder than can be studied and their data pooled. These linkage-based approaches can provide a relatively well-defined chromosomal location for single-gene conditions and has led to successful gene-finding for cystic fibrosis, neurofibromatosis, and hundreds of additional, mostly rare, conditions. This approach can also be applied to common but genetically complex traits for which there are no simple inheritance patterns. This technique may require hundreds of small families, and the resultant gene localization is imprecise. A second method for gene localization can make use of small chromosome rearrangements, such as balanced translocations or small deletions or duplications that result in a phenotype for a known disorder. In these cases, the location of the chromosomal rearrangement immediately suggests that a gene at or near that rearrangement is etiologic and can be used to again directly search for evidence of a specific gene and mutation in that region. A third approach involves an unbiased search across the entire genome, utilizes whole genome or exome sequencing, and applied “filters” that narrow the number of potential variants based on assessing frequency of variants among normal, inheritance patterns, and “in silico” predictions of protein changes that result from the variant in the genetic code (Davis et al., 2014; Francescatto and Katsanis, 2015).

Making a Diagnosis in the Human Genome Era

In infants suspected of having a genetic disease, knowing the etiology can inform subsequent care, both for treatment and prevention of problems associated or anticipated (Coulter et al., 2011; Willig et al., 2015). The broadening knowledge of disorders linked with variants (such as those listed in OMIM), the increasing availability, and decreasing cost of sequencing since completion of the Human Genome Project have increased the use of extensive sequencing

and have led to questions of when extensive sequencing should be carried out relative to more familiar testing including karyotypes and chromosomal microarrays (Stavropoulos et al., 2016).

Traditionally, genetic testing in infants suspected of having a genetic variation-related condition has started with a chromosomal karyotype, or fluorescence in situ hybridization (FISH) testing for aneuploidy, or other chromosomal anomalies such as chromosomal rearrangements and large gains and losses in chromosomal material. The tests sometimes were used to confirm readily apparent family history and clinical picture suspicions that fit a known syndrome or disorder. Clinicians would also order a chromosomal microarray first when the clinical picture and history do not provide support for a known single gene (e.g., cystic fibrosis, Meckel–Gruber syndrome, etc.) or environmental exposure (fetal alcohol, congenital rubella, etc.) or when a known chromosomal disorder such as one of the aneuploidies (trisomy 18 or 21, etc.) is suspected. In many cases the mother may have already had an analysis carried out as part of prenatal screening that may also inform the diagnostic strategy. CNVs can identify high-resolution gains and losses in genetic material, including insertions and deletions (indels) (Miller et al., 2010). Chromosomal microarrays are used to assess infants with multiple anomalies and may identify up to 20% of potentially causative genetic variations (specific variants at a single nucleotide or insertions, deletions, or CNVs that have previously been associated with disease phenotype). Much progress has come as the chromosomal microarray has evolved to include oligonucleotide and single nucleotide probes that identify both single nucleotide variants as well as CNVs (including microduplication and microdeletion syndromes with high sensitivity and specificity) (Miller et al., 2010). While microarrays have greatly improved, the sequence of karyotype, FISH, and microarray is now in some transition, as cost and time to complete whole exome and whole genome sequencing are both rapidly decreasing.

Applying Exomes and Whole Genome Sequences in Clinical Management

First-tier tests such as karyotypes and chromosomal microarrays identify only 20%–25% of genetic variations likely to be contributing to developmental delay, congenital malformations, metabolic disorders, or other problems of extreme phenotype suspected to be genetically related. The addition of whole exome and whole genome sequencing is gathering additional information that is increasing the rate of identified likely causative variants (Lee et al., 2014; Yang et al., 2014; Stavropoulos et al., 2016). The tools of whole exome and even whole genome sequencing are now being applied clinically in cases where a genetics cause is suspected but where CNV analysis or the clinical presentation does not provide a specific answer. While these applications are costly and still generate discussion about when and how to apply them, the trend currently would seem to favor their increasingly widespread application to cases in the nursery and beyond (Shashi et al., 2014; Petrikin et al., 2015). If costs of sequencing drop below the \$100 range and the time to complete sequence and informatics filtering to identify DNA variants drops from weeks and months to a day or two, sequencing may become very widespread. That said, cost and time for genotyping and analysis to identify rare, potentially causative variants will not be the only considerations for this application of sequencing. The ethical issues of incidental findings arising from whole genome and whole exome sequencing will need to be addressed. For example, whole exome sequencing can disclose risks mostly applicable only in adult life (*BRCA1* mutation risks

for breast cancer, for example) that will be far in the future for the neonate tested but of potential immediate impact for the parent who is a likely carrier but may be unaware of (and potentially uninterested in knowing) this risk. Guidelines for responses to these incidental or secondary findings in neonates are evolving (Bortkin et al., 2015; Bortkin and Rothwell, 2016; Lantos, 2016).

The first clinical report of whole exome sequencing leading to a clinical diagnosis was a 15-month-old boy with failure to thrive and an inflammatory bowel disease–appearing phenotype. Multiple diagnostic tests had failed to identify a specific etiology, so his providers completed exome sequencing. The sequencing identified over 10,000 variants, but “filtering” to identify variants that were nonsynonymous, rare (occurring in less than 1% of the population), and predicted to cause changes in proteins that could alter function, narrowed the list of candidates to one novel, hemizygous missense mutation in the X-linked inhibitor of an apoptosis gene with a known central role in proinflammatory response and bacterial sensing (Wortheley et al., 2011). Since this first case, thousands of whole exome and whole genome sequences have been completed, and groups are reporting improved rates of finding likely causative variants (Yang et al., 2013, 2014).

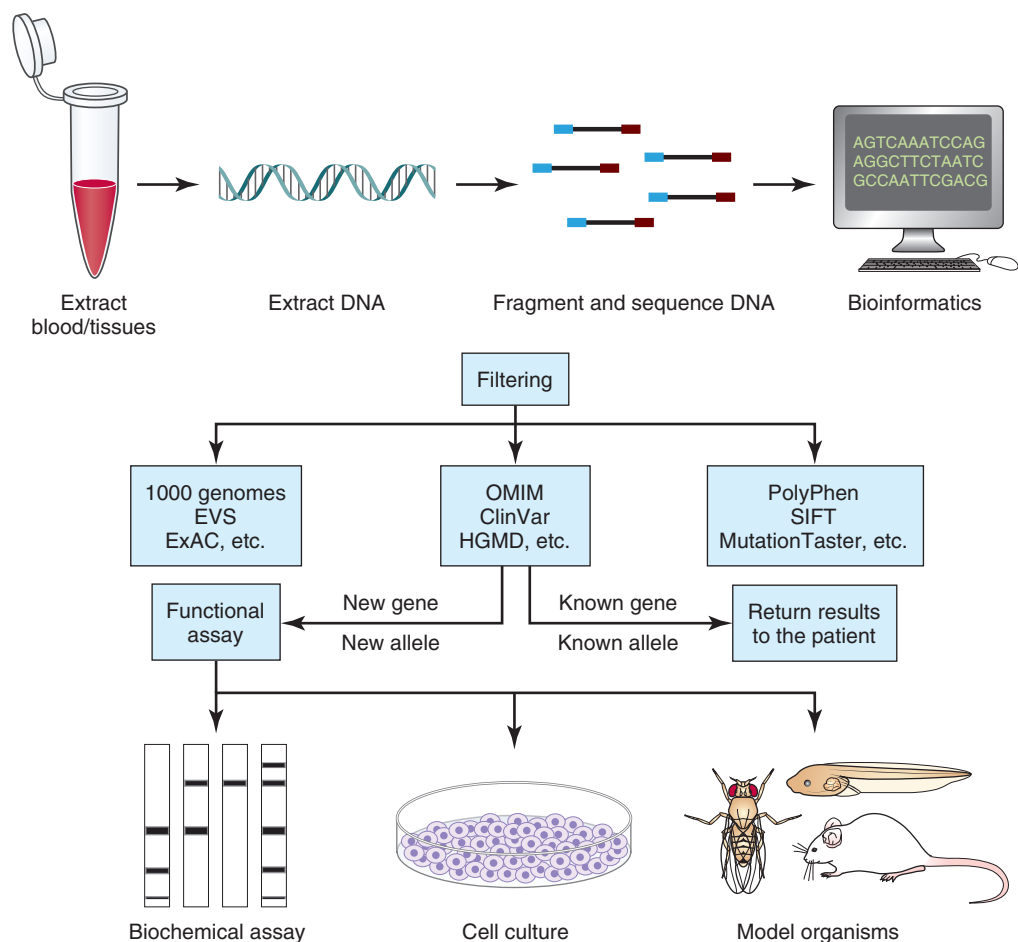

For clinicians, the processes used and standards applied to define *de novo* variants discovered by extensive sequencing as “causative” are of primary importance, as presence of causative alleles will likely drive healthcare and reproductive decisions. These processes and standards to determine functional relevance or causation are evolving and nonuniform. However, the process can be summarized as sequencing, followed by identification of all variants from reference sequences, and then filtering to a much smaller number of variants that are rare, known to be disease-causing, or are likely, through prediction modeling, to alter function. The process has been helped by informatics and collaboration. In the simplest case, some mutations identified in whole genome or whole exome sequencing can be identified as disease causing or disease linked by comparing with databases such as OMIM, ClinVar, and the Human Gene Mutation Variant database. In cases where no mutations are identified that have been previously linked with disease, exome or whole genome sequence variants can be assessed for their population frequency by comparison with thousands of normal healthy individuals’ sequences in the 1000 Genomes and Exome Variant databases, with the assumption that disease-causing variants are likely to be extremely rare or never reported in the populations catalogued in the publicly available datasets. The prediction of protein function alterations for the rare or *de novo* variants identified by sequencing can be predicted by tools such as PolyPhen, SIFT, and Mutation Taster. The American College of Medical Genetics and Genomics (ACMG) recommends use of specific standard terminology—*pathogenic*, *likely pathogenic*, *uncertain significance*, *likely benign*, and *benign*—to describe variants identified in genes that cause Mendelian disorders and provides a system for classifying variants into these five categories based on criteria using typical types of variant evidence (e.g., population data, computational data, functional data, segregation data) (Richards et al., 2015). The next level of prediction of causality, beyond the epidemiologic and genetic–protein structural predictions, comes with validation using *in vivo* models such as zebrafish, flies, and rodents (Francis et al., 2015) (Fig. 17.2).

Whole exome and whole genome sequencing are becoming a clinical reality in the nursery for newborns with congenital anomalies and extreme phenotypes suspected to be caused by genetic variants. The next step could be the inclusion of sequencing of every newborn as part of newborn screening. The goal of newborn screening is

to test for multiple (currently ~ 50 in most states) disorders that benefit from early detection and intervention. With rapid sequencing and filtering through available sequencing data to identify variants in genes already known to be linked with disease, this approach could provide prediction and diagnosis for thousands of conditions that could benefit from early detection and intervention or, for known lethal conditions, allow for earlier implementation of holistic care emphasizing quality of life and parental and family bonding choices to be made (Petrikin et al., 2015).

The rapid sequencing approach has been tested utilizing the “50 hour genome” in a select group of infants and their parents in an intensive care nursery. Success of this approach relies on much more than simply the sequencing and filtering of the genome. Clinicians had classified the neonate’s presenting clinical features in specific Human Phenotype Ontology terminology. This phenotype information was then mapped to informatics tools, either local or publicly available, and then a rank-order list of over 5000 monogenic disorders was matched with the neonate’s phenotype. Sequencing results were compared with reference sequences to identify insertions, deletions, and variations in sequence. This first-level filter identified several million variants, which were further filtered to identify those with population frequency less than 1% and categorized to American Society of Human Genetics criteria 1–3, which are (1) high likelihood of being pathogenic, (2) likely pathogenic, or (3) unknown significance. The next step was to match the neonate’s phenotype with the variant’s likely causative phenotype. Likely causative variants were then further scrutinized by a panel of experts, and the likely variants that emerged were confirmed by independent resequencing. In the first report of 35 ill infants, all less than 4 months old, 20 (57%) had causative variants identified. Average age at testing was 26 days, and median days to a confirmed, reported diagnosis was 23. Most (65%) were *de novo* variants. Almost half of the infants diagnosed by whole genome sequence lacked phenotypic traits that would have predicted the variant being causative, suggesting either that the phenotype had not yet developed or that there was phenotypic pleiotropy or variant phenotype with the genotype (Willig et al., 2015). PhenomeCentral is a web portal (<https://phenomecentral.org>) where clinicians and rare disease scientists can meet and exchange phenotypic and relevant genetic information from exome sequences or candidate gene testing. It includes information from several rare and undiagnosed disease programs worldwide (Buske et al., 2015).

Two sources of challenge, dilemma, or opportunity are readily identifiable with genome-wide or exome-wide testing. First is what to do with the variants of unknown significance that were also identified. The conventional approach is to not report these results to family but to maintain and continuously check these variants for disease associations as more sequences and phenotypes are accumulated worldwide and disease-variant links can be established. Currently, more than 20 novel disease gene discoveries or substantive phenotype expansions of previously known gene–phenotype associations are reported each month (Petrikin et al., 2015). The second dilemma is whether or not to inform parents of sequence variants in genes that are not related to the conditions that led to sequencing but have been previously identified as likely to be causative of preventable or manageable disease. These variants, previously termed *incidental* or *secondary variants*, have now been classified by the ACMG as secondary variants. There are 56 genes at present identified. The current guidance from the ACMG is that a qualified genetics healthcare professional should obtain written informed consent for the sequencing. The process should

• **Fig. 17.2** Next-Generation Sequencing Linking Variants With Disease. Next-generation sequence workflow complemented with functional studies. Upon consent of family members, collection of either blood or tissue is performed, followed by extraction of DNA. The DNA is then fragmented, and a sequence library is subjected to massively parallel sequencing. Resulting reads of the DNA sequences are then processed and curated and compared against existing human genetic databases to identify possible candidate variants that have previously been associated with human genetic disease. The identification of genes or alleles not previously implicated in human genetic disease requires functional assays to test variants' pathogenicity. EVS, Exome variant server; ExAC, Exome Aggregation Cexomonsortium; HGMD, Human Gene Mutation Database; OMIM, online Mendelian inheritance in man. (Modified from Francescatto L, Katsanis N. Newborn screening and the era of medical genomics. *Semin Perinatol.* 2015; 39: 617–622.)

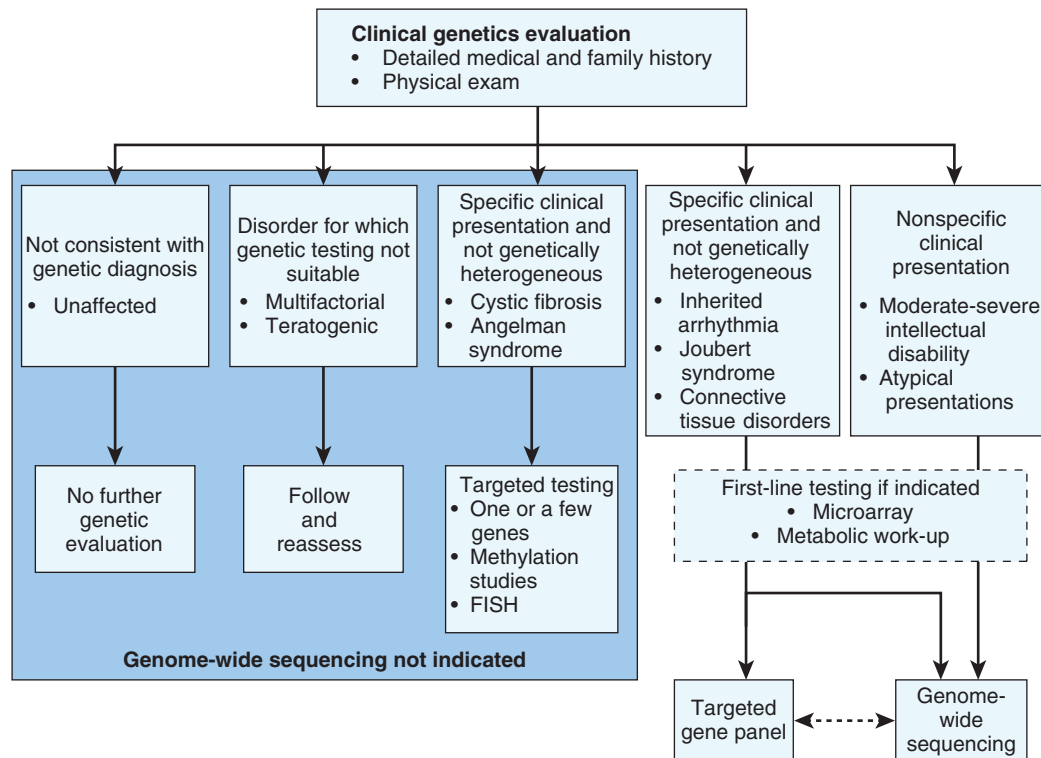

include information about uncertainty around interpretation of results, especially with rare variants in previously undescribed genetic associations and the potential for the impact that findings may have on other family members. As for secondary findings, ACMG recommends that parents be given the choice to opt out of notification of these findings, for their child and for themselves (as sequencing to diagnose neonatal conditions often includes sequencing of the neonate and both parents) (ACMG Board of Directors, 2015).

The Canadian College of Medical Geneticists has also provided guidance on genome-wide sequencing use for identifying suspected monogenic disease. Their Clinical Indications Working Group lists aspects of familial history and clinical conditions that are likely to be identified via a genome-wide or exome-wide sequencing approach (Table 17.1). They also provide guidance on which type of disorders warrant consideration of the sequencing approach early in the diagnostic work-up (Fig. 17.3). Their guidance regarding secondary or incidental findings for children is that incidental results that reveal risk for a highly penetrant condition that is medically actionable during childhood should be reported to the parents.

TABLE 17.1 Characteristics Suggesting Likelihood of Monogenic Disease or Facilitating Interpretation of Genome-Wide Data

| | |
|-------------------------|---|
| Family history | Similar affected individuals Recognizable inheritance patterns Consanguinity |
| Phenotype | Severity Specificity of clinical presentation (e.g., neuropathy, seizures, metabolic disease) |
| Clinical interpretation | Careful phenotyping (detailed physical exam, imaging studies, blood chemistries) Normal chromosomal microarray and other relevant laboratory testing Exclusion of acquired causes such as infection |

From Boycott K, Hartley T, Adam S, et al. Canadian College of Medical Geneticists. The clinical application of genome-wide sequencing for monogenic diseases in Canada: Position Statement of the Canadian College of Medical Geneticists. *J Med Genet.* 2015; 52: 431–437.

• **Fig. 17.3** Example of a Decision Aid to Facilitate the Diagnostic Evaluation of Patients With Rare Disease of Suspected Monogenic Etiology From the Canadian College of Medical Geneticists. Decision aid to facilitate the diagnostic evaluation of patients with rare disease of suspected monogenic etiology. This decision aid highlights where genome-wide sequencing may prove useful in the evaluation process. The conditions listed in each box are representative examples only. For specific clinical presentations associated with genetic heterogeneity, the decision regarding the use of a targeted panel versus genome-wide sequencing is dependent on a number of factors, including the availability of the testing options and the yield of such panels. Patients with negative targeted gene panels may benefit from subsequent clinical genome-wide sequencing. Conversely, consideration of a targeted panel subsequent to uninformative clinical genome-wide sequencing would be dependent on the depth of coverage achieved in the latter instance. *FISH*, Fluorescence in situ hybridization. (Adapted from Boycott K, Hartley T, Adam S, et al. Canadian College of Medical Geneticists. The clinical application of genome-wide sequencing for monogenic diseases in Canada: Position Statement of the Canadian College of Medical Geneticists. *J Med Genet.* 2015; 52: 431–437.)

A child's risk for adult-onset genetic conditions should not be communicated unless (1) the parents request the disclosure and (2) disclosure could prevent serious harm to the health of a parent or family member—determined on an individual, case-by-case basis. The Canadian guidance is that there is no obligation to re-contact children after they become adults to let them know of potentially later-onset monogenic diseases (Boycott et al., 2015).

Complex Common/Multigenic Diseases of Newborns

In addition to the diseases and disorders directly linked to genetic variants, there are strong indications that genetic variations contribute to risks of the common complex diseases associated with prematurity, including retinopathy of prematurity, necrotizing enterocolitis, sepsis, IVH, and BPD (Bhandari and Gruen, 2015). These indications include higher prevalence of the disorder among monozygotic compared with dizygotic twins. There is also variation in risk associated with ancestry (Jo, 2014).

Efforts to identify genetic links with the major morbidities of prematurity were based on testing SNPs in “candidate genes” that

were best-guess genes based on their assumed contributions to the morbidities of inflammation, coagulation, vascular development, or extreme phenotypes noted in Mendelian diseases (Hartnett et al., 2014; Bhandari and Gruen, 2015; Ment et al., 2015). While some of these investigations identified associations with *P* values of less than .05 between presence of the minor allele (the less frequently appearing variant allele in the population) and the morbidity, the studies were frequently limited by sample size, major differences between case and control populations, and uncertainty about defined phenotypes. Prior experience indicated that replication of such associations was unlikely, and identification of genetic links with complex common diseases such as macular degeneration and type 2 diabetes in adults was being uncovered by assessing large populations with genome-wide genotyping and testing for associations (Ioannidis et al., 2001; Wellcome Trust Case Control Consortium, 2007).

As previously noted, finding genetic variants associated strongly with relatively common complex traits is difficult. The challenge derives at least in part because variants in different genes may each contribute to the odds of developing the disease, and each gene's contributions may depend on interaction with environmental

contributors. This heterogeneity creates substantial difficulties in finding and confirming that any single gene or variant plays a role in the disease of interest. One approach to rapidly screen millions of relatively common (occurring in more than 1% of the population) variants for association with disease is called *genome-wide association study*, or *GWAS*. The GWAS approach has been enabled by (a) the growing number of sequenced individuals of different ancestral backgrounds which allows quantification of variant frequency, (b) advances in technology allowing for relatively inexpensive and rapid genotyping of millions of genotypes from samples collected from thousands of cases and controls, and (c) advances in statistical techniques which allow researchers test associations between genotyped and imputed variants and the disease phenotype of interest (Manolio et al., 2009).

The prerequisite to the comprehensive search for variation was the development of the human haplotype map, or “HapMap” (<http://hapmap.ncbi.nlm.nih.gov/>). The HapMap project developed a comprehensive understanding of the relationship of SNPs across multiple human ancestral groups that included Europe, Africa, and Asia (International HapMap Consortium, 2007). In essence, haplotypes are groupings of SNPs that travel together, i.e., when the locus for SNPA is an “A,” the locus for SNPB is also an A, and the locus for SNPC is a “G.” This AAG combination is termed a *haplotype*. HapMap is an essential component of a GWA study because it provides a comprehensive reference listing of the relationships of SNPs and CNVs to enable their careful characterization in case and control populations with enhanced power by taking advantage of the human genome’s patterns of linkage among SNPs. By looking for evidence of DNA sequence variation or allelic or haplotype variation in which one allele is found significantly overrepresented in a case compared with a control population, there is a strong suggestion that the etiologic gene and variant lie in the vicinity of the surrogate or marker gene allele.

One challenge of the GWA study is that while it can identify one or more loci associated with the disease, implementation of a GWA requires expensive technology and large (usually numbering in the thousands), well-phenotyped case and control populations. Thousands of cases and controls must be available to have sufficient power to detect the small effects seen. A second caveat is that the loci found usually have low relative risks (RRs) or odds ratios (ORs) so that the clinical effect of any one identified locus is very small (Hardy and Singleton, 2009). However, collections of loci can have a combined substantial impact, and even a low OR may identify a new biologic pathway that could provide great insights into etiology and treatment (Hirschhorn, 2009). Besides detecting disease-associated genetic risk factors, these studies also contribute to knowledge of the genetics of normal trait variation, such as height and skin color. Using GWAs, more than 50 genes were found to have a role in factors such as height determination (Hirschhorn and Lettre, 2009). However, although identical twin studies tell us that height is almost entirely genetically determined across a broad range of environmental variation, the genetic findings to date explain only a small amount of the contributors to height. There is still much to learn in regard to normal trait variation and the ability to make predictions about a child’s future physical traits or cognitive behavioral range. New approaches beyond GWA are still critically needed to find this large amount of unexplained genetic contributors, but these may possibly be addressed with sequencing of the whole genome or whole exome (Manolio et al., 2009).

Results of GWA studies that tested millions of SNPs for association with the phenotypes IVH and BPD have been published (Hadchouel et al., 2011; Ambalavanan et al., 2015; Ment et al.,

2015). For BPD, one SNP in one gene (*SPOCK2*) has been identified as having variants associated with BPD, and within the same study, the association was as strong among white subjects as African subjects (Hadchouel et al., 2011). A second GWA study which utilized the State of California’s newborn screening blood spots could not replicate the *SPOCK2* associations and did not identify any other SNPs associated with BPD with P values less than 10^{-6} (Wang et al., 2013). Most recently, Ambalavanan et al. reported on a cohort of 1000 extremely low birth weight infants and was also not able to replicate the *SPOCK2* associations in the US cohort; however, in pathways analysis, 77 biologic pathways were associated with BPD, including the microRNA miR-219 pathway, which had the strongest association with severe BPD. When mild BPD and severe BPD were analyzed separately, the pathways segregated almost completely (only three were shared). There were also differential associations noted among different racial and ethnic groups (Ambalavanan et al., 2015). In addition to genome-wide testing for associations between SNPs and BPD, one group tested associations between CNVs and BPD and found no associations that reached genome-wide significance levels (Hoffmann et al., 2014). In another cohort, associations between CNVs in three regions were associated with BPD. Fifteen of the 21 genes represented in these regions differ in expression between the pseudoglandular and canalicular phases of lung development (Ahmad et al., 2016). If the analysis is expanded to the wider level of the entire exome, one group has reported assessment of 26 premature neonates with severe BPD and identified unique rare variants in *NOS2* (inducible nitric oxide synthase), matrix metalloproteinase 1 (*MMP1*), *CRP* (C-reactive protein), *LBP* (lipopolysaccharide-binding protein), and the toll-like receptor (*TLR*) family (Carrera et al., 2015). The group from California that completed the GWA study and CNV analysis has also reported results of exome sequencing on 50 BPD-affected and unaffected premature neonates and identified 258 genes with rare nonsynonymous mutations in patients with BPD. The identified genes with variants included genes involved in collagen tissue organization and lung structural development (Li et al., 2015). The findings of the GWA study, exome, CNV, and pathways analyses strongly suggest that the heritability of BPD risk is complex and is linked to uncommon variation in genes involved in one or more pathways involved with any of the complex components of lung organ development. Many more infants will have to be consistently assigned phenotypes and have sequencing completed in order to identify the most common pathways implicated in development of BPD.

Variants in three coagulation genes have been frequently studied for their associations with IVH in preterm infants. The candidate genes are the factor V Leiden (*F5*) variant, polymorphisms of the methylene-tetrahydrofolate reductase gene (*MTHFR*), and the prothrombin 20210G>A variant (*F2*). They have had interesting, but not always replicated, associations. In addition, variants in *COL4A1* have been associated with severe IVH in preterm and term born neonates and were found to be clustered in families; however, in larger cohorts, these associations have not always been replicated. In addition to BPD, severe IVH is the only other major morbidity of prematurity to be tested with unbiased GWA. Over one million SNPs were assessed for GWA with severe IVH in a well-phenotyped cohort. A significant 10-SNP haplotype in the region on chromosome 1 between the genes *GM140* (also known as *LINC01699*, long intergenic non-protein coding RNA 1699) and *CACNA1E* (calcium channel, voltage dependent, R type and alpha 1E subunit) was determined to be strongly linked with severe IVH, but the association was not replicated in a small cohort (64 cases, 226 controls) (Ment et al., 2015).

While these studies show promise in identifying regions in the genome linked with significant morbidity and interactions among gene variants in biologic pathways, the consistent message is that the discovery of compelling and actionable genetic links with the complex common morbidities of prematurity will not be simple. While we have found rare variants linked with very specific phenotypes—for example in severe respiratory distress syndrome and progressive pulmonary disease—the best chance to identify variants that contribute to a significant number of premature neonates who develop a major morbidity remains the assembly of very well-phenotyped study cohorts, accurate genotyping, and a willingness among investigators to share data for testing and replication of findings.

Guidelines and Recommendations for Integration of Genomics Into Practice

With the rapid introduction of whole exome and whole genome sequences into clinical medicine, clinical geneticists and generalist pediatricians and neonatologists, as well as families and numerous other caregivers, are faced with an enormous amount of information that provides a limited amount of specific actionable data and a much vaster amount of information of unclear meaning. In an effort to give some guidance, stakeholders from a variety of disciplines and perspectives met and developed guidelines for how to apply the current (2016) state of genomics in clinical medicine. In the current clinical setting, since these fields move so rapidly, it is important to maintain close collaborations between caretaker clinicians such as neonatologists or other pediatricians and clinical/molecular geneticists who can provide optimal guidelines on the best tests to order in any challenging situation and how to interpret the sometimes complex results.

Prenatal Identification of Genetic Disorders

The application of array and sequencing technologies has also revolutionized the field of prenatal testing in recent years with noninvasive prenatal diagnosis now becoming the norm for identification of aneuploidies (Evans et al., 2016). Ultrasound and maternal serum testing continue to be important methods applied at a population level to screen for those structural abnormalities (e.g., neural tube defects, omphalocele, cleft lip/palate, congenital heart disease, renal anomalies, etc.) that in many cases are developmental disruptions without a known gene specific cause. Beyond the detection of aneuploidies that rely on the presence of fetal DNA in the maternal circulation, it has even become possible, currently as a research tool, to carry out whole genome sequencing of the fetus to detect single-gene defects (Kitzman et al., 2012). As with newborn screening by whole genome sequencing, the sequencing of a fetus's whole exome is equally fraught with ethical and social issues beyond the mere technical challenges that are now being surmounted. The future use of these approaches will depend on both solving the technologic challenges and developing consensus views on the best ethical approaches (Tabor et al., 2012).

The Future

As technologies advance, genetics is increasingly moving from advances in diagnostics to therapeutics. Cell-based therapies,

advances in bone marrow transplantation, direct treatment of metabolic disorders, and mutation-specific interventions for cystic fibrosis and Duchenne muscular dystrophy have all provided hope to families with a child in whom diagnosis, but not curative therapy, was once the rule. Now a new technology, Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR)/CRISPR-associated protein-9 nuclease (Cas9) (Sternberg and Doudna, 2015), holds out a new promise that targeted gene editing may be possible to apply on an individual basis. This approach, first associated with an immune function found in bacteria, may enable defective genes to be readily cut out and replaced by the normal DNA sequence. However, as with any new advance, clinicians need to walk the line between enthusiasm and hope promised by the new discoveries and the realities of how long it can take to move from the lab to the clinic in applying new findings to ensure they are safe, effective, and ethically applied. Nonetheless, the experience of the last several decades of human genome research holds even greater promise for the future.

Prenatal Diagnosis

EDITH Y. CHENG

KEY POINTS

- All pregnant women have the option to undergo prenatal screening/diagnosis for genetic conditions and/or birth defects.
- Specific indications for genetic counseling and prenatal diagnosis options include a history of chromosome abnormality, Mendelian genetic disorder, or metabolic disorder; increased risk for neural tube defect; abnormal maternal serum screening test; or a fetal anomaly suspected/diagnosed on ultrasound.
- Successful prenatal diagnosis requires a known condition associated with a structural abnormality visible in the fetus, a biochemical abnormality in amniotic fluid/amniocytes, or a known molecular mutation.
- Preimplantation genetic screening/diagnosis selects out embryos with a genetic condition or aneuploidy and transfers either chromosomally normal embryos or embryos without the at-risk genetic condition.

Background

In the late 1970s, only two programs comprised the paradigms in prenatal screening/diagnosis: (1) elevated maternal serum alpha fetoprotein (MSAFP) to screen for neural tube defects (NTs) and (2) maternal age over 35 years at delivery to screen for Down syndrome (DS). Neither program used imaging routinely, and only second trimester amniocentesis for fetal karyotyping was available. Today, more than 45 years later, genomic discoveries and advances in fetal imaging technology present women with many prenatal screening and/or diagnostic options for the evaluation of their fetus for birth defects and/or genomic abnormalities and, in some cases, provide an opportunity for in utero treatment. Early diagnosis of birth defects broadens the scope of management options and allows preparation for delivery and postnatal support, all of which have improved viability and outcome of serious birth defects that in previous decades would be termed prenatally as “lethal anomalies.” The care of the mother–fetus dyad is now multidisciplinary, through partnerships between maternal–fetal medicine, neonatology, pediatric surgery, and pediatric subspecialists. The goal of this chapter is to discuss the breadth of prenatal diagnosis to illustrate the complexity of the technology and choices, recognize their benefits, accuracy, and limitations, and understand their impact in the care of pregnancies with genetic disorders or fetal anomalies.

Principles of Prenatal Screening and Diagnosis

Screening is the systematic application of a test to identify individuals at high risk for an asymptomatic, well-defined, severe medical condition with an established incidence, for which identification would lead to prevention and/or treatment. The screening test should be cost effective, simple and safe, readily available and accessible, and should have a well-defined performance. An accurate diagnostic test should be available to confirm or refute the screen positive result. In prenatal screening programs, there should be timely transfer of test results, counseling, respect for the ethical and cultural values and decisions of patients, and full discussion of all options if the suspected condition is confirmed.

Diagnosis of a suspected condition in an at-risk fetus requires a known diagnosis for which the condition is associated with a detectable abnormality either within the fetus and/or the fetal tissues. This could be in the form of a structural abnormality readily seen on ultrasound (that appears at the appropriate developmental stage of the system affected), a cytogenetic abnormality, a biochemical abnormality in the amniotic fluid or in cultured amniocytes, a genomic duplication or deficiency identified on microarray analysis, or a known mutation associated with the condition. For example, a mother with autosomal dominant achondroplasia has a 50% chance of having an affected child. Knowing that in an affected fetus the long bones do not demonstrate growth deceleration until after 24 weeks' gestation, a normal growth ultrasound at 20 weeks' gestation would not be reassuring, but a normal growth ultrasound at 30 weeks' gestation would essentially exclude the diagnosis in her fetus. Conversely, if she had a known mutation for achondroplasia, genetic testing of chorionic villi retrieved at 13 weeks' gestation or amniocytes retrieved by amniocentesis at 16 weeks would inform the status of the fetus before the condition is visible prenatally.

Invasive Prenatal Diagnostic Procedures

Midtrimester Genetic Amniocentesis

The term *amniocentesis* refers to the procedure of removing amniotic fluid under ultrasound guidance from the uterus. It is performed for many reasons, including determination of fetal lung maturity

for decisions regarding delivery of a late preterm infant or measurement of bilirubin in the amniotic fluid as a surrogate for fetal anemia in pregnancies complicated by Rhesus D (RhD) isoimmunization. Between 15 and 20 weeks' gestation, amniocentesis is performed, predominantly for prenatal diagnosis. The amniotic fluid contains desquamated cells from fetal skin, bladder, and the gastrointestinal tract, which serve as sources for cytogenetic and enzymatic/biochemical studies. DNA can also be extracted from these cultured amniocytes for genomic studies. Proteins such as alpha fetoprotein (AFP) and acetylcholinesterase are measured to confirm an NTD suspected on ultrasound.

The benefits of second trimester amniocentesis include its large international clinical experience of over 40 years, the standardization of culture and cytogenomic techniques, which decrease the culture failure rate to 0.1%, and its diagnostic accuracy, broad availability, and relative safety (Winsor et al., 1999). Based predominantly on data obtained in the 1980s and 1990s, when second trimester amniocentesis was widely performed, the incidence for minor complications such as cramping and leakage of fluid immediately after the procedure was collectively about 1%, while the incidence of significant complications such as chorioamnionitis and/or miscarriage was 0.25%–0.5% (Centers for Disease Control and Prevention, 1995).

The only large randomized study of complications associated with second trimester amniocentesis, completed on 4606 low-risk women (aged 25–34 years), observed a pregnancy loss rate of 1.7% in the study group after amniocentesis compared with 0.7% in the control group; in this study however, an 18-gauge needle was used (Tabor et al., 1986). The procedural-related risk was revisited through the multicenter First Trimester and Second Trimester Evaluation Risk (FASTER) trial in 2004, which observed a loss rate after second trimester amniocentesis (and before 24 weeks' gestation) of 0.06% or 1/1600 (Eddleman et al., 2006). The earlier and higher reported fetal loss rate likely reflects the nuances that contribute to the safety of any procedure that requires technical expertise: the 16-year period between 1990 and 2006 was a time when noninvasive screening with cell-free DNA (cfDNA) was not available, and prenatal diagnosis for trisomy 21 and other fetal anomalies required invasive procedures. In the United States, maternal serum screening for DS with a screen positive rate of 5% was universally recommended and broadly adopted. Ultrasound guidance, use of a 22-gauge needle, and a large volume of patients at a referral institution allowed practitioners to maintain their technical skills. Each institution should calculate its own complication rate. In 2008, Odibo and colleagues reported on a single center's 16-year experience and identified a fetal loss rate of 0.13% or 1/769 (Odibo et al., 2008). A 2015 metaanalysis of miscarriage after amniocentesis in more than 42,000 women who had the procedure—compared with 138,000 who did not—estimated the procedural loss rate to be approximately 0.11% or 1/900 (Akolekar et al., 2015). These data support that midtrimester amniocentesis is safe when the procedure is performed by experienced providers in large volume referral centers. Thus the current estimated procedural risk discussed with patients is approximately 0.1%–0.3 %.

Early amniocentesis, performed between 11 and 14 weeks' gestation, was briefly explored in the late 1990s. The only large prospective study, the Canadian Early and Mid-Trimester Amniocentesis Trial, randomized 4334 women to early amniocentesis versus midtrimester amniocentesis and observed a higher pregnancy loss rate, more rupture of membranes, more culture failures, and greater procedural difficulty in the early amniocentesis group (The Canadian Early and Mid-Trimester Amniocentesis Trial [CEMAT] Group,

1998; Johnson et al., 1999). An unanticipated observation was a 1.3% incidence of club feet when early amniocentesis was performed between 11 and 13 weeks' gestation, compared with 0.1% after midtrimester amniocentesis.

The timing of second trimester amniocentesis is based on a number of factors. The uterus prior to 15 to 16 weeks of gestation is still within the maternal pelvis and not easily accessible (Fig. 18.1). At midtrimester the volume of amniotic fluid is about 150–300 mL, with the fetal kidneys beginning to produce urine (Fig. 18.2). There is uncertainty about the rate of fetal urine production in early pregnancy, but at 25 weeks' gestation, the fetal urine output appears to be about 110 mL/kg per 24 hours. For fetal karyotyping and genomic studies, approximately 20–40 cc of amniotic fluid is necessary to obtain an adequate number of amniocytes for culture in order to provide results with appropriate accuracy and confidence. While midtrimester amniocentesis has not been associated with permanent structural or functional consequences to the exposed fetuses, the association of early amniocentesis with a 10-fold increase in club feet demonstrates the importance of an adequate amount of amniotic fluid at this developmental stage for normal orthopedic development of the fetus. Midtrimester amniocentesis performed later, at 18 to 22 weeks' gestation, is technically easier, and there is less concern for removing 40 cc of amniotic fluid. However, cases requiring complex molecular testing may involve weeks of analysis, thus extending completion of testing late in pregnancy and potentially limiting management options.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) involves the aspiration of the chorion frondosum either transabdominally or transcervically between 10 and 13 weeks' gestation (Fig. 18.3). Trophoblasts and mesenchymal core cells of the chorionic villi provide actively growing cells for karyotype and genomic analyses and biochemical/enzymatic studies. In contrast to second trimester amniocentesis, mosaicism (the finding of two or more cell lines with a different chromosome constitution—usually trisomy) occurs in about 1%–2% of cases (Goldberg and Wohlferd, 1997). Because the cell types represent both extraembryonic and embryonic tissue, resolution of a mosaic CVS result requires identification of the source of the chromosome abnormality by completing an amniocentesis and, in some cases, fetal blood sampling for karyotype. As a result of CVS, the developmental processes of *confined placental mosaicism*, *trisomic rescue*, and *uniparental disomy* were discovered (Kalousek and Vekemans, 1996). Depending on the placental cell lineage from which the chromosome abnormality was derived, confined placental mosaicism could result in (1) generalized mosaicism affecting both the placenta and fetus; (2) mosaicism in the placenta only and a diploid/chromosomally normal fetus; (3) chromosome abnormality confined to the placenta with a chromosomally normal fetus; or (4) chromosomally normal placenta and a mosaic fetus. Trisomic rescue refers to the process by which the zygote began as a trisomic conceptus and, through postzygotic loss of the extra chromosome, became diploid while the placenta remained mosaic or completely abnormal. The clinical consequence of trisomic rescue is chromosome dependent because some genes require the presence of both maternal and paternal copies to express a normal phenotype. In the case of chromosome 15, for example, if CVS demonstrated mosaicism for trisomy 15 and genetic amniocentesis demonstrated that the fetus was diploid for chromosome 15, studies to confirm biparental inheritance must be completed to predict a normal fetal

• **Fig. 18.1** Midtrimester Genetic Amniocentesis Under Ultrasound Guidance.

• **Fig. 18.2** Volume of Amniotic Fluid Across Fetal Gestation. (Adapted from Bruce RA, Wolf EF. Normal amniotic fluid volume changes throughout pregnancy. *Am J Obstet Gynecol.* 1989;161:382–388.)

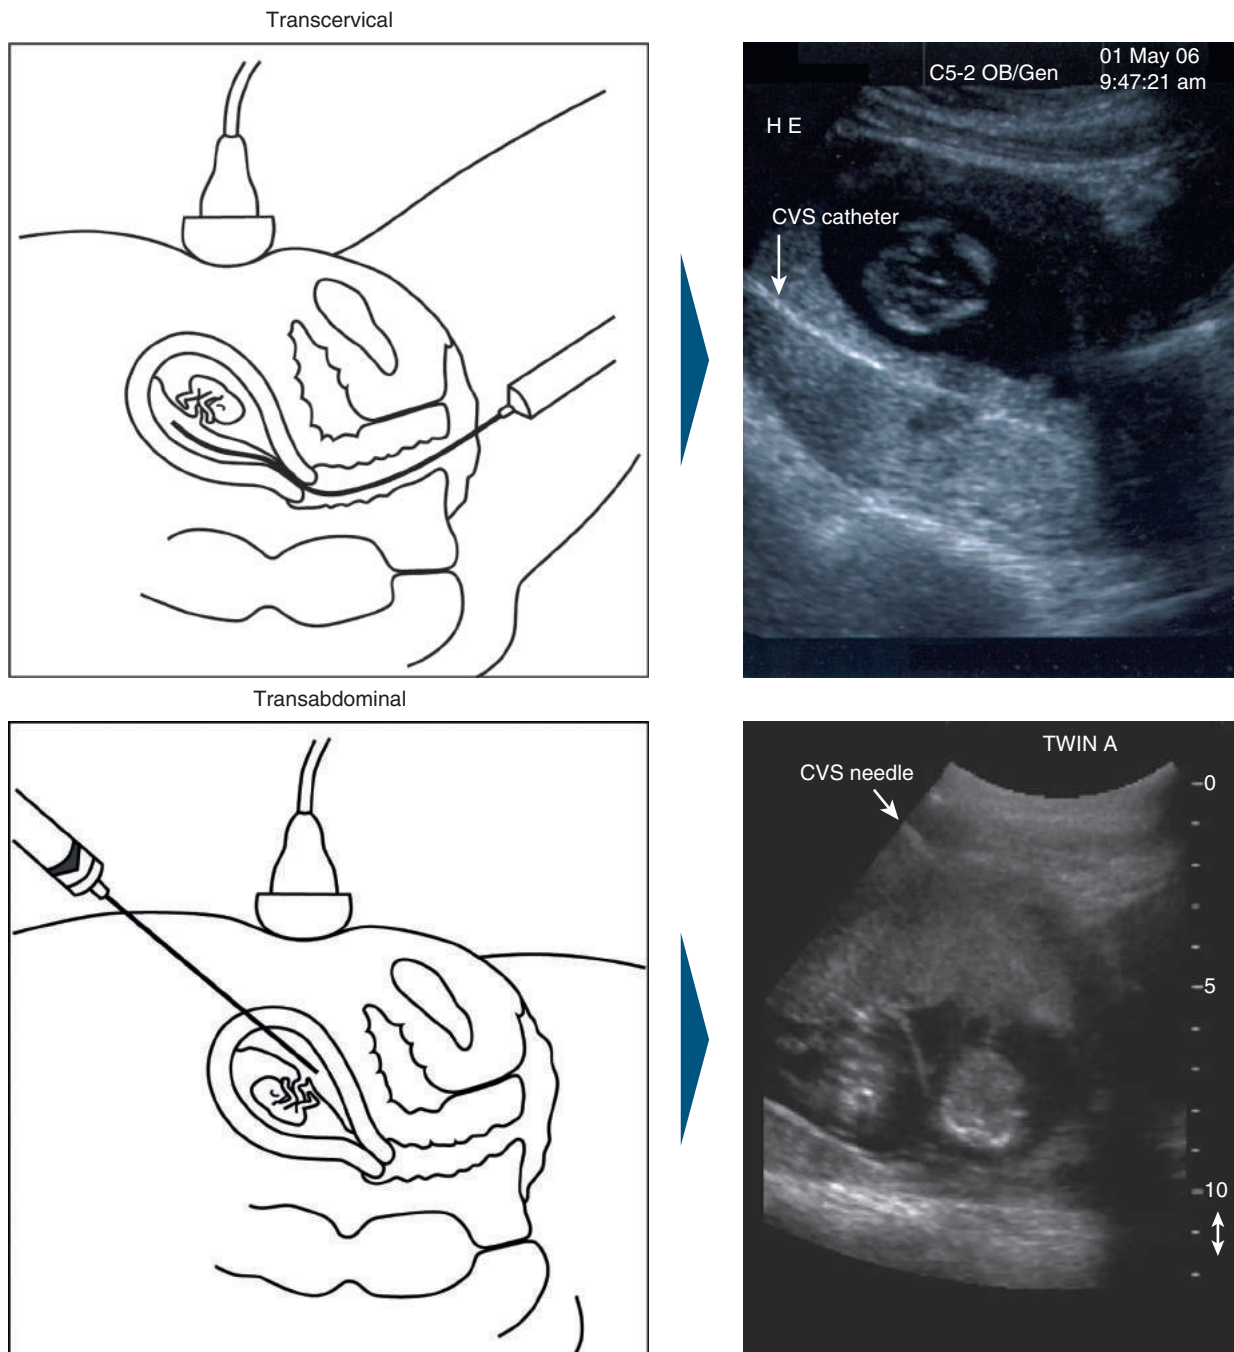

phenotype. However, if the fetus contained two maternal copies of chromosome 15, it would be predicted to have Prader–Willi syndrome or Angelman syndrome if it had two paternal copies of chromosome 15.

CVS is associated with a pregnancy loss rate of about 1/500 (Akolekar et al., 2015). It requires operator expertise and continuous ultrasound guidance. Maternal cell contamination studies are completed to discriminate between female fetal results and contamination from maternal cells. CVS allows for early diagnosis at a time when the privacy of the pregnancy can still be maintained and should be considered if complex diagnostic strategies (requiring time) are anticipated. Because CVS is dependent on operator expertise within a small gestational age window, it is not readily accessible to all patients.

Characteristics of midtrimester amniocentesis and CVS are compared in Table 18.1.

Percutaneous Umbilical Cord Blood Sampling

Fetal cordocentesis or percutaneous umbilical cord blood sampling (PUBS) was introduced in 1985 (Daffos et al., 1985). The ease of DNA-based testing for genetic conditions has essentially replaced

• **Fig. 18.3** Transcervical and Transabdominal Chorionic Villus Sampling Under Ultrasound Guidance. CVS, Chorionic villus sampling.

PUBS as a diagnostic tool in prenatal diagnosis. Today, the sampling of fetal blood is most commonly used for the diagnosis of fetal anemia or thrombocytopenia. As a therapeutic tool, it is used for in utero transfusion of blood or platelets and, rarely, for administration of antiarrhythmic medications for the treatment of fetal tachyarrhythmias. The procedure is completed under continuous ultrasound guidance with a 22-gauge spinal needle placed into the umbilical vein and can be performed beginning at approximately 18 weeks' gestation and subsequently throughout the remainder of the pregnancy. Before 18 weeks' gestation, the fetal umbilical vein may be too small although our group has completed a successful transfusion of a 16-week hydropic fetus due to Kell isoimmunization;

in this type of urgent situation, direct transfusion into the fetal heart is also possible. Exanguination (if the cord is lacerated), periumbilical vein hematoma in Wharton jelly, preterm rupture of membranes, preterm labor, or placental abruption are some of the complications of PUBS. The procedure requires operator expertise and the risk of the procedure is about 1%.

Genetic Testing of the Fetus

Fetal karyotyping still has a role in prenatal diagnosis and can be completed on chorionic villi, amniocytes, and fetal blood. Interphase fluorescent in situ hybridization (IFISH) with small

TABLE 18.1 Characteristics of Midtrimester Amniocentesis and Chorionic Villus Sampling for Prenatal Diagnosis

| | CVS | Amniocentesis |
|---|-------------|---------------|
| Gestational age at procedure | 10–13 weeks | 15–20 weeks |
| Miscarriage rate | 1/500 | 1/500–1/800 |
| Culture mosaicism | 1%–2% | 0.1% |
| Turnaround time | 7–10 days | 7–14 days |
| Diagnostic accuracy | >99% | >99% |
| IFISH | + | + |

CVS, Chorionic villus sampling; IFISH, interphase fluorescent in situ hybridization.

chromosome-specific DNA probes (10–300 kb) is used for rapid confirmation of suspected aneuploidy in uncultured amniocytes (Fig. 18.4). Historically, IFISH has been used for identification of extra chromosome material and specific submicroscopic gene deletions associated with genetic disorders. Today, this cytogenetic tool has been largely replaced by microarray analyses that expose genomic deficiencies and duplications that are smaller than those previously identified by IFISH. In cases in which a genetic condition is not associated with a known mutation, biochemical and enzymatic/functional studies of cultured amniocytes may be the only means for prenatal diagnosis for the condition in question.

Microarray Technology

Chromosomal microarray (CMA) technologies are bridges between cytogenetics and molecular genetics. They have greater resolution than traditional cytogenetics and are platforms designed to measure DNA regions for gains or losses across the entire genome simultaneously. The utility of microarray technology has been thoroughly evaluated in the postnatal and adult population and now replaces the standard banded karyotype that geneticists have relied on since the 1970s. CMA is now the first-line diagnostic test for individuals with autism spectrum disorder and unexplained birth defects and/

• **Fig. 18.4** Interphase Fluorescent In Situ Hybridization on Uncultured Amniocytes. The hybridization process takes approximately 24 hours after which the signals are counted for diagnosis.

or cognitive delay (Miller et al., 2010). Compared with standard karyotyping, CMA detects a causative genomic imbalance in an additional 10%–15% of these patients. In 2010, the American College of Medical Genetics issued practice guidelines for array-based technology in clinical medical genetics and supported CMA as the first-line test for the investigation of individuals with developmental delay and/or congenital anomalies (Manning and Hudgins, 2010).

In December 2013, The American College of Obstetricians and Gynecologists and the Society for Maternal–Fetal Medicine issued a joint committee opinion on the use of CMA analysis in prenatal diagnosis (American College of Obstetricians and Gynecologists Committee on Genetics, 2013; South et al., 2013). In a large multicentered trial supported by the Eunice Kennedy Shriver National Institute of Child Health and Human Development, CMA was found to perform just as well as standard karyotyping in the diagnosis of common aneuploidies in fetal samples (from CVS or amniocentesis) from women undergoing prenatal diagnosis (Wapner et al., 2012). In pregnancies with normal ultrasounds that had been referred for standard indications such as advanced maternal age or positive screening for DS, CMA yielded clinically relevant information in an additional 1.7% of pregnancies. However, in pregnancies with abnormal ultrasounds and a normal karyotype, CMA identified clinically significant genomic changes in an additional 6% of pregnancies, although it did not identify triploidy and balanced translocations. The added value of prenatal microarray analysis is further supported by DeWit and colleagues who, in a systematic review of the literature up to 2013, reported genomic imbalances in 3.1%–7.9% of fetuses with an isolated ultrasound abnormality and normal karyotype (DeWit et al., 2014). The value of microarray analysis is also seen in the genetic evaluation of stillbirths. Reddy and colleagues found that microarray analysis yielded more relevant genetic information than karyotyping in term stillbirths with or without anomalies, even after correcting for aneuploidy (Reddy et al., 2012).

Although there is no consensus regarding the type of array platforms used in prenatal diagnosis, *high-density single nucleotide polymorphism (SNP) arrays* are now becoming the platform of choice, as they allow for greater in-depth coverage of the genome to reveal smaller duplications and deficiencies. In addition, SNP arrays have the advantage of detecting long continuous stretches of DNA homozygosity (identical DNA sequences between a pair of chromosomes). These findings could reveal uniparental disomy, as seen in rare genetic conditions such as Angelman syndrome, as part of the work-up for confined placental mosaicism, or could uncover consanguinity.

Because the mechanisms causing genetic conditions are diverse and complex, no microarray platform will be completely diagnostic. Genetic conditions not associated with a relative change in DNA sequences will not be identified. Depending on the platform used, low level mosaicism and genomic regions not represented by the platform may not be detected. Tetraploidy may not be detected. Other mechanisms of genetic disease such as point mutations, methylation disorders, and mitochondrial disorders cannot be uncovered using microarray technology. In addition, as the resolution of the technology improves, secondary and incidental findings, both with and without known clinical implications, will arise as the genome is searched. Copy number variants not previously reported in established databases are referred to as *variations of unknown significance*. For these reasons, women should have pretest and posttest genetic counseling to discuss expectations and limitations of microarray testing in their pregnancy.

Exome Sequencing

Exome sequencing focuses on targeted sequencing of the protein coding regions of the genomic DNA and shows promise as a new tool in gene discovery for complex diseases and for facilitating the accurate diagnosis of individuals with unsolved Mendelian conditions. Yang and colleagues presented convincing data on 250 patients with suspected but undiagnosed genetic conditions in which exome sequencing was performed (Yang et al., 2013). Eighty-six mutated alleles were discovered and considered highly likely to be causative in 62 of the 250 patients, achieving a 25% molecular diagnostic success rate.

Application of exome sequencing in prenatal diagnosis is increasing as families and clinicians wish to uncover a genetic explanation for observed fetal anomalies. In a 2015 publication describing 24 fetuses with ultrasound abnormalities, exome sequencing provided a definitive genetic diagnosis in five fetuses (Drury et al., 2015). Currently, exome sequencing is used as a research tool and/or as a “second tier” test for phenotypes for which no diagnosis has been made using conventional microarray platforms.

Noninvasive Prenatal Screening

Maternal Serum Screening

Second trimester maternal serum screening for abnormal fetal conditions in the 1970s preceded ultrasound and focused on identifying fetal NTD through elevated MSAFP. An elevated MSAFP level of 2.5 multiples of the median (MoM) or greater generally signals a pregnancy that should undergo further evaluation. Because AFP is a circulating protein in the fetus, any disruption in the integrity of the fetal body, such as an open NTD, gastroschisis, or omphalocele and some dermatologic disorders, will be associated with elevations of AFP in maternal serum and amniotic fluid. Other considerations for elevated MSAFP are incorrect dating of the pregnancy, multiple gestation, impending fetal demise, and history of vaginal bleeding.

In 1984, screening for DS and trisomy 18 because of low MSAFP was added (Merkatz et al., 1984). Other analytes, human chorionic gonadotropin (hCG), unconjugated estriol (UE3), and inhibin-A (INH), were subsequently added to improve the detection rate (DR) for DS (Fig. 18.5). The patterns of serum analyte levels for NTD, DS, and trisomy 18 are illustrated in Fig. 18.6. Trisomy 18 has a unique pattern in that all of the analytes are low; however, INH is not measured because it does not increase the discriminatory value of this pattern for trisomy 18. Analyte levels are reported in MoM to standardize the gestational age dependency of the interpretation of the levels. Likelihood ratios (LRs) are calculated for each analyte based on a comparison of the proportion of affected and unaffected pregnancies with the same MoM value. The final risk or adjusted risk (AR) is then a product of the patient's background risk ($BR = \text{maternal age-related risk}$) and the four LRs generated by the four second trimester analytes (MSAFP, hCG, UE3, INH) ($AR = BR \times LR1 \times LR2 \times LR3 \times LR4$). For example, a 30-year-old woman has an a priori risk of 1/900 for DS at term. If she completed a second trimester of the four serum analytes (also known as the Quad Screen), and the LRs for MSAFP, UE3, hCG, and INH were 1.7, 10.5, 2.0, and 1.0, respectively, then her AR for DS at term would be 1/25, similar to someone who is 45 years or older. A DS risk of 1/270 at midtrimester or greater is considered a positive screen, and additional testing should be offered.

• **Fig. 18.5** Evolution of Maternal Serum Screening for Neural Tube Defect and Down Syndrome. *AFP*, Alpha fetoprotein; β -*hCG*, β -human chorionic gonadotrophin; *DS*, Down syndrome; *MSAFP*, maternal serum alpha fetoprotein; *NT*, nuchal thickness; *NTD*, neural tube defect; *PAPP-A*, pregnancy-associated plasma protein-A.

• **Fig. 18.6** Serum Analyte Patterns for Down Syndrome, Trisomy 18, and Neural Tube Defect. Dimeric inhibin-A is not interpreted for trisomy 18 because of the unique analyte pattern for trisomy 18 and does not increase the detection rate for trisomy 18. *AFP*, Alpha fetoprotein; *hCG*, human chorionic gonadotrophin; *INH*, inhibin-A; *UE3*, unconjugated estriol.

In the first trimester, three additional markers, fetal nuchal thickness (NT) measured by ultrasound, maternal serum pregnancy-associated plasma protein-A (PAPP-A), and *hCG* are used to calculate LRs to adjust the patient's risk. The combination of all the components of the first and second trimester screening elements, known as the Integrated Screen, provides the highest DR for DS when a 5% screen positive rate is used (Malone et al., 2005). However, many options for screening are available depending on gestational age at entry to prenatal care, access to first trimester ultrasound for NT evaluation, and patient desire for information at different stages of her pregnancy (American College of Obstetricians and Gynecologists, 2007). Components of the screening options for DS are outlined in Table 18.2.

Prenatal Fetal Imaging

First trimester NT or thickness refers to the measurement of the normal subcutaneous fluid-filled space at the back of the fetal neck between 10 and 14 weeks' gestation. In normal fetuses, the maximal thickness increases with increasing gestational age as defined by the crown rump length (CRL). An increased NT is associated with DS and is now used in conjunction with maternal age and first and second trimester maternal serum analytes to provide the highest DR for DS (Malone et al., 2005). An LR is generated for NT measurement based on CRL and incorporated into the AR calculation. Other chromosome abnormalities, fetal anomalies, and poor pregnancy outcomes are also observed with increasing NT (Souka et al., 2005) (Fig. 18.7).

NT measurement is obtained by transabdominal imaging of the pregnancy, and its success as a screening tool depends on the accurate procurement of images for measurement, which is

TABLE 18.2 Screening Options for Down Syndrome and Their Detection Rates

| Screening Test | Detection Rate (%) |
|---|--------------------|
| First Trimester^a | |
| • NT measurement alone | 64–70 |
| • NT, PAPP-A, <i>hCG</i> | 82–87 |
| Second Trimester^b (Serum) | |
| • Triple screen (<i>AFP</i> , <i>hCG</i> , <i>UE3</i>) ^c | 69 |
| • Quad screen (<i>AFP</i> , <i>hCG</i> , <i>UE3</i> , inhibin-A) | 81 |
| Integrated Screening Options | |
| • First and second trimester serum only | 85–88 |
| • NT + first and second trimester serum | 94–96 |
| Other Options | |
| • Stepwise sequential screen | 95 |
| If first trimester positive screen, offer diagnostic test | |
| If first trimester negative screen, continue as Integrated Screen | |
| • Contingent/first trimester only | 88–94 |
| If first trimester positive, offer diagnostic test | |
| If first trimester negative, no further screening | |

^aFirst trimester = 11–14 weeks' gestation.

^bSecond trimester = 15–22 weeks' gestation.

AFP, Alpha fetoprotein; *hCG*, human chorionic gonadotrophin; *NT*, nuchal thickness; *PAPP-A*, pregnancy-associated plasma protein-A; *UE3*, unconjugated estriol.

dependent on the size and position of the fetus, maternal habitus, and operator performance. Operator performance is audited for quality following formal training and certification of competency. The FASTER trial and the Fetal Medicine Foundation study observed the highest success rates in obtaining NT measurements at the first patient visit when the CRL was between 45 and 84 mm, corresponding to 11 weeks 3 days and 14 weeks 2 days of gestation respectively (Malone et al., 2004). The additional benefit of completing the ultrasound in this gestational age window is the opportunity to confirm pregnancy viability and identify other fetal anomalies such as anencephaly, abdominal wall defects, and possibly congenital heart defects.

Other ultrasound findings in the first trimester fetus that may be associated with DS include *absent* or *hypoplastic nasal bone*, *abnormal ductus venosus blood flow*, and *tricuspid regurgitation*. Initially thought promising, the role of absent or hypoplastic nasal bone as an independent marker for DS in a general low-risk population screening program is unclear, because of ethnic variation in nasal bone size and the difficulty in obtaining acceptable images (Malone et al., 2004). However, the nasal bone is absent in 70% of DS fetuses, 55% of trisomy 18 fetuses, and 35% of trisomy 13 fetuses (Cicero et al., 2001). Both abnormal flow of the ductus venosus and tricuspid regurgitation in the first trimester have been associated with fetuses at high risk for chromosome abnormalities (Matias et al., 1998a; Matias et al., 1998b; Huggon et al., 2003). Because these studies were completed by experienced sonographers and were performed on high-risk fetuses only, this information may not be applicable to a general low-risk population.

The scope of information regarding *second trimester ultrasonography for aneuploidy screening and diagnosis of fetal anomalies* is too

| Nuchal thickness | Chromosomal defects | Normal karyotype | | |
|------------------|---------------------|------------------|---------------------------|----------------|
| | | Fetal death | Major fetal abnormalities | Alive and well |
| <95th %ile | 0.2% | 1.3% | 1.0% | 97% |
| 95th–99th %iles | 3.7% | 1.3% | 2.5% | 93% |
| 3.5–4.4 mm | 21.1% | 2.7% | 10.0% | 70% |
| 4.5–5.4 mm | 33.3% | 3.4% | 18.5% | 50% |

broad and complex to cover in this chapter. In the United States, prenatal diagnosis units follow the practice guidelines developed in conjunction with the American College of Radiology, the American College of Obstetricians and Gynecologists, and the Society of Radiologists in Ultrasound (*American Institute of Ultrasound in Medicine*, 2013). The following discussion summarizes some key concepts in prenatal diagnosis and second trimester imaging of the fetus.

In addition to an increased first trimester NT, DS fetuses can exhibit other abnormalities in the second trimester that would adjust the patient's a priori risk. [Table 18.3](#) provides an overview of the common ultrasound markers and their LR's (*American College of Obstetricians and Gynecologists*, 2016). Note that some of these markers signal other pathologic processes. Therefore it is important to consider the entire breadth of diagnoses for some of these markers. Calculation of DS AR based on markers can be performed at <http://perinatology.com/calculators2.htm> (Age Adjusted Ultrasound Risk Assessment).

Accurate identification of fetal NTD can be readily accomplished in the second trimester ultrasound. This is especially important for maximizing management options for the pregnancy in light of the availability of in utero fetal surgery for repair of the defect (*Adzick et al.*, 2011). The “lemon” sign representing scalloping of the frontal bones and the “banana” sign representing obliteration of the cisterna magna with distortion of the cerebellum due to herniation of the hindbrain (Chiari malformation) are the two most sensitive and specific findings for an open NTD. Observation of these cranial defects should initiate a detailed survey of the fetal spine. Mild ventriculomegaly in the second trimester is variably observed in only 70% of cases. The location and extent of the defect are important for

TABLE 18.3 Ultrasound Markers Associated With Aneuploidy and Down Syndrome

| Marker | Likelihood Ratio |
|---|---------------------------------|
| Cystic hygroma (first trimester) | >50% aneuploid, Turner syndrome |
| Isolated echogenic intracardiac focus (second trimester) | 1.4–1.8 for DS |
| Renal pelviectasis ≥ 4 mm (20 weeks' gestation) | 1.5–1.6 for DS |
| Echogenic bowel ^a | 5.5–6.7 for DS |
| Ventriculomegaly (10–15 mm) | 25 for DS |
| Isolated choroid plexus cyst(s) (≤ 20 weeks' gestation) | No association |
| Short femur length (< 2.5 %ile for gestational age) | 1.1–2.2 for DS |

^aGrade 3 = density same as bone.
DS, Down syndrome.

anticipation of postnatal bowel and bladder function, ambulation, neurocognitive development, and consideration for in utero fetal surgery. Amniocentesis is recommended to confirm an open defect by demonstrating elevated amniotic fluid AFP levels and presence of acetylcholinesterase and to exclude fetal genomic abnormalities, which are found in 10% of fetuses with an open NTD (*Sepulveda et al.*, 2004). Eligibility for fetal surgery includes a chromosomally normal fetus diagnosed between 19 weeks 0 days and 25 weeks 6

days with an isolated myelomeningocele between T1 and S1, with evidence of hindbrain herniation in a nonobese (body mass index <35) healthy woman with no history or risk factor for preterm delivery. Among children who underwent in utero surgery for repair of spina bifida between 19 and 25 weeks' gestation under the Management of Myelomeningocele Study (MOMs trial), there was a 50% reduction in the need for a ventricular shunt, less Chiari malformation, and improved motor skills, with twice as many children walking independently at 30 months compared with the postnatal surgery group (Adzick et al., 2011).

First and second trimester ultrasounds readily diagnose *anencephaly*, *fetal gastroschisis*, and *fetal omphalocele*. The gestational age at which nuchal thickness (NT) screening is performed is especially efficient in excluding these conditions. Early diagnosis of fetal anencephaly maximizes management options and decreases maternal complications. Large gastroschises are readily suspected during the evaluation of the NT. Fetal omphaloceles may be ambiguous in the first trimester because of the physiologic herniation of the midgut into the base of the umbilical cord before 12 weeks' gestation. After 12 weeks, the gut returns to the abdominal cavity; persistence of a midline abdominal wall sacular defect with the umbilical cord arising from the apex of the sac and abdominal contents in the sac is diagnostic of an omphalocele. In contrast, gastroschisis is typically paraumbilical to the right of the cord insertion with free floating eviscerated bowel in the amniotic fluid. It is important to differentiate between these two anatomic defects; gastroschisis is generally isolated and rarely associated with fetal chromosome abnormalities. However, this condition is associated with a high rate of intrauterine growth restriction, oligohydramnios, and intrauterine fetal demise; prenatal care pathways for surveillance may be helpful in optimizing the fetus for postnatal interventions. In contrast, omphaloceles are strongly associated with other pathologic processes including other structural anomalies and genomic or syndromic conditions. Amniocentesis is recommended to exclude an underlying genomic imbalance that could impact postnatal interventions and prognosis. Fetuses with gastroschisis tolerate labor and vaginal delivery well, while fetuses with large omphaloceles are delivered by cesarean section because of the risk of rupture during vaginal delivery.

Prenatal skeletal dysplasia should be suspected when the long bone measurements are at or less than the 5th percentile or more than three standard deviations below the mean for gestational age (Krakow et al., 2009). Concurrent abnormalities such as fractures (osteogenesis imperfecta types II–IV), shape of the skull (thanatophoric dwarf), or decreased mineralization (hypophosphatasia) may direct the diagnosis. However, the diagnosis of most nonlethal congenital skeletal dysplasias will not be made until after birth or even into adulthood. Thus prenatal diagnosis of skeletal dysplasias centers around the probability of lethal pulmonary hypoplasia, which directs the prenatal and postnatal management of the pregnancy.

To date, two-dimensional ultrasound remains the standard imaging modality for prenatal screening and diagnosis. Three-dimensional ultrasound is helpful in visualizing any external structural abnormalities such as cleft lip/palate and spina bifida. The use of fetal magnetic resonance imaging is increasing and is most helpful in evaluating fetal intracranial abnormalities suspected on ultrasound.

Cell-Free DNA (Noninvasive Prenatal Testing)

cfDNA analysis in maternal plasma is used in noninvasive prenatal testing (NIPT) with greatest focus on prenatal detection of

aneuploidy for chromosomes 13, 18, 21, and X. In pregnancy, approximately 3%–20% of the total cfDNA in maternal plasma is derived from the pregnancy (Lo et al., 1997; Lun and Chiu, 2008). Although many refer to this as “free fetal DNA,” the DNA is in fact derived *primarily from the placenta*, which serves as a surrogate for the fetus and is cleared from the maternal circulation within hours after delivery (Lo et al., 1997). The molecular principle behind NIPT is the measurement of relative amounts of circulating free placental DNA compared with the amount of circulating free maternal DNA. In other words, a pregnancy at 14 weeks affected with DS will show an excess of DNA fragments for chromosome 21, assuming that the mother does not herself have DS or is not mosaic for DS.

The positive predictive value (PPV) using cfDNA screening in women aged 40 years is 87% for DS, 68% for trisomy 18, and 57% for trisomy 13; for women aged 25 years, the PPV for DS was 33%, 13% for trisomy 18, and 9% for trisomy 13 (Meck et al., 2015). Wang and colleagues also evaluated the test performance of cfDNA screening in high-risk pregnancies and found a poor performance for sex chromosome aneuploidy, with a PPV of only 39%, because the sex chromosome aneuploidy may reflect the mother rather than the fetus (Wang et al., 2015). False-positive and false-negative results may be related to fetal mosaicism, vanishing twin, confined placental mosaicism, unsuspected maternal chromosome abnormality, and unsuspected maternal malignancy (Amant et al., 2015). For these reasons, the American College of Obstetricians and Gynecologists and the Society for Maternal–Fetal Medicine strongly recommend that NIPT should “be an informed patient choice after pretest counseling and should not be part of routine prenatal laboratory assessment.” They further recommend that “a patient with a positive test result should be referred for genetic counseling and should be offered invasive prenatal diagnosis for confirmation of test results” (American College of Obstetricians and Gynecologists, 2015).

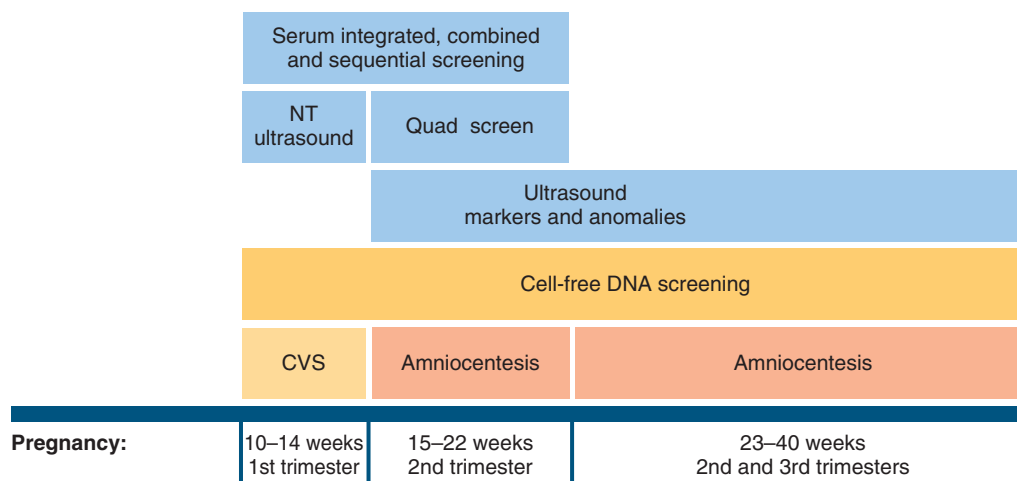

Other considerations in the performance of cfDNA screening include its dependency on gestational age and “fetal fraction.” Low fetal fraction (defined as less than 4% fetal DNA in maternal serum) is inversely associated with maternal body mass index (Table 18.4) (Wang et al., 2013; Norton et al., 2015). In a study of 222,384 pregnancies, Wang and colleagues identified that at 10 to 11 weeks' gestation, the median percentage of fetal DNA in maternal serum is about 10% and increases at a rate of 0.1% until

TABLE 18.4 Relationship Between Maternal Weight and Adequate Fetal Fraction (>4%) in Maternal Serum

| Maternal Weight (kg) | Adequate Fetal Fraction (%) ^a |
|----------------------|--|
| <70 | >99 |
| 71–80 | 99 |
| >90–100 | 96 |
| >100–110 | 95 |
| >140 | 71 |

^aAssuming ≥4% fetal fraction.

• **Fig. 18.8** Prenatal Screening and Testing Options During Pregnancy. NT, nuchal thickness; CVS, chorionic villus sampling.

21 weeks' gestation; after 21 weeks, the rate of increase is 2% per week (Wang et al., 2013). Two percent of pregnancies during the 10 to 21 gestational-week period had less than 4% "fetal" cfDNA (Wang et al., 2013). In a secondary analysis, of a large randomized comparison of cfDNA screening and traditional first trimester screening with NT measurement and maternal serum analytes in low-risk women, Norton and colleagues discovered that among women in whom there were no results on cfDNA testing, the prevalence of aneuploidy was 2.7% (1/38), which is significantly higher than expected (1/236, 0.4%) for this low-risk group of women (Norton et al., 2015). Specifically, for women with a "fetal" fraction less than 4%, 4.7% (9/192) had aneuploidy, although six of these cases were detected by standard screening. Nonetheless, the high prevalence of aneuploidy in noninformative cases (due to low "fetal" fraction) may reflect aberrant biology of the aneuploid placenta.

cfDNA screening currently offers reliable information about the three most common aneuploidies. However, in a recent review of 220 chromosome abnormalities identified prenatally between 2009 and 2014, cfDNA testing did not detect about half of the clinically significant chromosome abnormalities that were found either by karyotyping or microarray (Shani et al., 2016). More importantly, 79% of the abnormalities were from pregnancies with abnormal serum screening and/or abnormal ultrasound findings. These findings underscore the fact that current cfDNA technology is a screening tool and does not have the breadth and depth to offer the scope of genomic information about the fetus with multiple complex anomalies that could be obtained through CVS or genetic amniocentesis. Although some companies are offering testing for selected microdeletion syndromes, these tests have not been validated clinically and should not be chosen for diagnosis of a fetus at known risk.

In summary, noninvasive prenatal screening has expanded to cover the entire course of pregnancy, allowing directed diagnosis of several common chromosomal conditions without invasive testing (Fig. 18.8). Points to consider when counseling for NIPT are found in Box 18.1. The next frontier in genomic medicine and prenatal diagnosis is clinical application of noninvasive sequencing of the entire prenatal genome for prenatal diagnosis (Fan et al., 2012; Kitzman et al., 2012).

• BOX 18.1 Noninvasive Prenatal Testing Counseling: Key Points

- Fetal fraction is inversely associated with maternal body mass index resulting in noninformative results.
- Performance of test not established for multiple gestations.
- Tests only for abnormal DNA quantities associated with chromosomes 13, 18, 21, and sex chromosomes.
- Does not test for other genetic conditions or genomic imbalances.
- No clinical validation for common microdeletion syndromes.
- Does not replace CVS or amniocentesis for direct analysis of genomic abnormalities.
- Confirmatory tests should be completed following a positive NIPT result, especially if there are no ultrasound abnormalities.
- Offers noninvasive testing at late gestations.
- Does not screen for neural tube defects: ultrasound and MSAFP should still be offered between 15 and 20 weeks.
- Family history should be obtained to determine if NIPT is the appropriate test for the patient.
- If patient presents in the first trimester, consider obtaining ultrasound for NT before offering NIPT.
- Genetic counseling should be provided to all patients considering NIPT.

CVS, Chorionic villus sampling; MSAFP, maternal serum alpha fetoprotein; NIPT, noninvasive prenatal testing; NT, nuchal thickness.

Preimplantation Genetic Diagnosis/Screening

Preimplantation Genetics

Preimplantation genetic diagnosis (PGD) and preimplantation genetic screening (PGS) require in vitro fertilization (IVF) technology and can be considered a form of prenatal diagnosis. Knowledge of the genetic mechanisms and risks for fetal anomalies as a function of the IVF and PGD/PGS processes is important as these women undergo prenatal screening with ultrasound, maternal serum screening, or NIPT. For the neonatologist, this background information may influence, for example, the suspicion that a newborn may have Beckwith–Wiedemann syndrome, since this syndrome

is associated with pregnancies achieved through IVF technologies. Women of advanced maternal age who achieve pregnancies using their own eggs often undergo PGS of the embryos for aneuploidy. Confirmatory testing by CVS or amniocentesis is recommended, but few women elect to undergo an invasive procedure that risks a much desired pregnancy. NIPT offers these women an intermediate solution for “confirmation” of a euploid fetus. However, knowledge of the number of embryos transferred and concordance with the number of viable fetuses seen on ultrasound are important if NIPT is used; an embryonic demise of a transferred twin could result in discordant NIPT results. Unique to IVF pregnancies, regardless

of whether embryos have undergone PGD or PGS, is the concern for genetic conditions and or birth defects as a result of imprinting errors or other mechanisms that may disrupt the normal developmental processes of the early embryo. Maternal serum screening for aneuploidy is not as robust in twin gestations as it is in singleton pregnancies. NIPT has not been validated in multiple gestations and is currently not recommended ([American College of Obstetricians and Gynecologists, 2015](#)). Thus ultrasound in some cases becomes the most reliable prenatal screening test for multiple gestations. Definitive prenatal diagnosis of twins discordant for birth defects still requires CVS or amniocentesis.

Summary

This exciting period of discoveries and advancements in prenatal diagnosis offers women a broad choice of studies to investigate the health of the fetus. For couples at high risk for a known condition, the option of PGD/PGS or DNA-based prenatal diagnosis offers them hope and a chance for a healthy baby. For fetuses with life-threatening structural anomalies, such as hypoplastic left heart syndrome, prenatal diagnosis offers preparation for delivery at a high-risk center where neonatal support and subspecialty intervention

offer the neonate a chance for survival. In these efforts, we have educated our patients and ourselves, for in the last 40 years we have had a window to peek into the developmental processes of the human embryo through imaging and genomics. Now, we have the potential to understand the action of developmental genes over time in both normal and abnormal conditions, along the fetal–pediatric–adult continuum.

The Dysmorphic Infant

CHAD R. HALDEMAN-ENGLERT, SULAGNA C. SAITTA, AND ELAINE H. ZACKAI

KEY POINTS

- A genetics evaluation should be considered for a patient in the setting of multiple anatomic anomalies, known maternal exposure to a teratogen, a history of familial disorders, increased carrier frequency or ethnic risk, or multiple pregnancy losses.
- The essential parts of a genetic evaluation include the medical history, family history, dysmorphism examination, literature review, and diagnostic testing.
- The best clues are the rarest and are generally the most helpful in establishing a differential diagnosis.
- The advancement of techniques utilized in genetic testing, such as chromosomal microarrays and next-generation sequencing, has greatly improved the ability to make a genetic diagnosis.
- In cases in which there is no clear diagnosis, prognosis and treatment should be determined according to the organ systems involved and the extent of their impairment.

Genetic disorders have a major impact on public health, as indicated by several large epidemiologic studies (Table 19.1) (Scriver et al., 1973; Hall et al., 1978; McCandless et al., 2004). Genetic factors may also contribute to more than two-thirds of the conditions prompting admission to a children's hospital (McCandless et al., 2004). Early identification of the genetic nature of a given condition may then help to appropriately focus resources for providing better care to these individuals. It is therefore critical to implement a systematic approach to evaluating a dysmorphic or malformed newborn. This chapter outlines such a general approach.

The clinical geneticist incorporates the following five essential tools in the evaluation of a child suspected of having a primary genetic disorder:

- History: prenatal, birth, and medical
- Pedigree analysis or family history
- Specialized clinical evaluation that includes a detailed dysmorphism examination
- Comprehensive literature search
- Genetic laboratory analyses (e.g., karyotype, chromosomal microarray, sequencing)

History

Prenatal

A complete gestational history should be generated, including results of prenatal testing such as maternal serum and noninvasive

prenatal screening, ultrasonography, and diagnostic genetic testing through chorionic villus sampling or amniocentesis (Box 19.1). The maternal age at conception should be documented, because the risk of chromosomal anomalies such as nondisjunction rises with maternal age. It is important to identify prenatal exposures to infection and medications, maternal habits such as alcohol and drug use, maternal chronic illnesses such as maternal diabetes, and pregnancy-related complications. An additional significant historical component involves the presence of abnormal levels of amniotic fluid. Oligohydramnios (decreased amniotic fluid volume) can be associated with either a fluid leak or a genitourinary abnormality, whereas polyhydramnios (excess amniotic fluid volume) can be seen in fetuses with neuromuscular disease or gastrointestinal malformations.

It is also important to identify exposure to environmental agents that might act as teratogens. Teratogens are environmental agents that may cause structural and functional diseases in an exposed fetus. Each teratogen may have a characteristic expression pattern, with a specific range of associated structural anomalies and dysmorphic features. Specific effects and the extent of those effects depend on the time of exposure, duration, and dosage as well as interactions with maternal and genetic susceptibility factors. In general, more severe effects are typically correlated with exposure early in the pregnancy and with more extensive (i.e., higher dose) exposure. The list of well-documented human teratogens is short and includes such substances as alcohol, thalidomide, warfarin, trimethadione, valproate, isotretinoin, and hydantoin. If history of an exposure is documented, an effort should be made to identify the developmental time and level of exposure. This information is critical, because the counseling and calculation of recurrence risk for a given malformation are vastly different if environmental exposures are involved.

Birth

Another important component of the gestational history is obtaining information on fetal activity, size, and position. Often the mother's subjective impressions can be further confirmed by examining obstetric records of the perinatal period. A history of hypotonia may be further supplemented by reports of poor fetal movements and breech presentation. Perinatal information including gestational age, fetal position at delivery, the length of labor, type of delivery, and any evidence of fetal distress, such as passage of meconium, are all relevant data (Box 19.2). Apgar scores, the need for resuscitation, birth parameters (weight, length, and head circumference), any malformations seen at birth, and all abnormal test results should be noted.

Medical

A full review of the medical issues of the child should include the baby's general health, test results, identification of any chronic medical issues, and need for hospitalization. Evaluation of growth, review of systems, developmental assessment, and notation of unusual behaviors can also provide important clues to a diagnosis.

Pedigree Analysis and Family History

A critical part of any genetic evaluation is the family history (Box 19.3); this is best accomplished by creating a three-generation pedigree, which is a schematic diagram depicting familial relationships using standard accepted symbols (Fig. 19.1). This formal

• **Fig. 19.1** Symbols commonly used for pedigree notation. (From Nussbaum RL, McInnes RR, Willard HF (eds). *Thompson and Thompson's Genetics in Medicine*, 7th ed. Philadelphia, PA: WB Saunders; 2007:117.)

record can also be used to summarize positive responses elicited during the interview. Special attention should be paid to ethnic origins of both sides of the family, consanguinity, and any first-degree relatives with similar malformations to those of the patient being evaluated, also known as the *index case*, *proband*, or *propositus*. An extended family history should be used to identify relatives with

congenital anomalies, developmental abnormalities, physical differences, or sudden death. Often photographs can provide clear objective evidence of a descriptive history.

Reproductive histories, especially of the parents, should be elicited. Specifically, questions should be asked about infertility, miscarriages, and stillbirths. The occurrence of more than two first-trimester miscarriages increases the probability of finding a balanced translocation in one parent (Campana et al., 1986; Castle and Bernstein, 1988). A balanced translocation is a rearrangement of genetic material such that two chromosomes have an equal exchange without loss or gain of material. There are typically no associated clinical features with such a rearrangement. However, when chromosomes align to recombine for meiosis in the sperm or egg, this exchange produces a risk of unequal distribution and an unbalanced translocation in the resulting fetus. In this case, there would be aneuploidy for part of a chromosome. It has been estimated that 25% of stillbirths exhibit single or multiple malformations, and in at least half of these cases there is a genetic etiology for the malformations. Couples with two or more pregnancy losses should undergo routine chromosome analysis or karyotyping. When possible, chromosome analysis such as a karyotype or microarray should be performed on the stillborn fetus or products of conception (ACOG Committee Opinion No. 581, 2013).

Obtaining a formal family history is helpful in discovering information that is often critical to making a diagnosis. Positive responses may help to discern a Mendelian pattern of inheritance for a given genetic disorder. For example, a disease affecting every generation, with both males and females involved, such as Marfan syndrome, displays an autosomal dominant pattern of inheritance. A pattern of X-linked recessive disease, such as hemophilia, instead shows affected males related through unaffected or minimally affected females; transmission in this pattern should not occur from father to son.

Physical Examination for Dysmorphology

A congenital malformation can be described as a “morphologic defect of an organ, part of an organ, or larger region of the body resulting from an intrinsically abnormal developmental process” (Jones et al., 2013). The term *dysmorphology* was introduced by Dr. David Smith in the 1960s to describe the study of human congenital malformations (Smith, 1966; Aase, 1990). This study of “abnormal form” emphasizes a focus on structural errors in development with an attempt to identify the underlying genetic etiology and pathogenesis of the disorder.

In a landmark study, Feingold and Bossert (1974) examined more than 2000 children to define normal values for a number of physical features. These standards were devised as screening tools to objectively identify children with differences possibly attributable to a genetic disorder. Important measurements include head circumference, inner and outer canthal distances, interpupillary distances, ear length, ear placement, internipple distances, chest circumference, and hand and foot lengths. Other graphs and measurements using age-appropriate standards can be found in compendia such as the *Handbook of Physical Measurements* (Gripp et al., 2013).

The assessment should begin with newborn growth parameters that can reflect the degree of any prenatal insult. Measurements such as height, weight (usually reflecting nutrition), and head circumference should be plotted on newborn graphs. Gestational age-appropriate graphs should be used for premature neonates. It is often helpful to express values that are outside the normal range

as 50th percentile for a different gestational age or in the number of standard deviations (SDs) above or below the mean. For example, a full-term baby with microcephaly may have a head circumference of less than the fifth percentile for 38 weeks. This degree of microcephaly could be stated more clearly if described as a specific number of SDs below the mean (e.g., -3 SD below the mean).

A complete physical examination should include assessment of patient anatomy for features varying from usual or normal standards. This assessment can often provide clues to embryologic mechanisms. The data obtained should then be interpreted using comprehensive standard tables that are available for these purposes. Special attention to familial variants should be given.

The shape and size of the head and fontanels should be noted as well as the cranial sutures, with assessment for evidence of craniosynostosis or an underlying brain malformation. Any scalp defects should also be documented. The shape of the forehead, appearance of the eyebrows (such as synophrys), and the texture and distribution of hair should be noted. The spacing of the eyes, or canthal measurements (Fig. 19.2), the interpupillary distance (Fig. 19.3; see also Fig. 19.2), palpebral fissure lengths (Fig. 19.4), presence or absence of colobomata and epicanthal folds, and determination of whether the palpebral fissures are turned upward or downward are components of the morphological examination of the eyes. Examination of the ears should include a search for preauricular and postauricular pits and tags, and assessment of the placement (Fig. 19.5), length (Fig. 19.6), and folding of the ear is important. Ear development occurs in a temporal frame similar to that of the kidneys during embryogenesis, and external ear anomalies can be associated with renal anomalies. Evaluation of the nose should cover the shape of nasal tip, the alae nasi, presence of anteverted nares, the length of the columella, and patency of the choanae. The mouth and throat are examined for the presence of a cleft lip or palate; the shape of the palate and uvula is noted, and the presence of unusual features, such as tongue deformities, lip pits, frenula, and natal teeth, are recorded. A small retrognathic or receding chin, which can be a part of several syndromes or an isolated finding, should be noted. The neck is inspected for excess nuchal folds or skin and for evidence of webbing. Any bony abnormalities in the neck should prompt an evaluation of the cervical vertebrae to confirm cervical and airway stability.

Evaluation of the chest and thorax involves lung auscultation and cardiac examination. Abnormal findings should prompt a consultation with a pediatric cardiologist and appropriate echocardiographic or invasive studies as needed. External measurements include determining the internipple distance and its ratio with respect to the chest circumference (Fig. 19.7). The abdominal examination is focused on determining whether organomegaly is present, a finding often associated with an inborn error of metabolism. The umbilicus should also be examined, with any hernias and the number of vessels present in the newborn cord being noted. A two-vessel cord, in which only a single artery is present, can be associated with renal anomalies. The genitourinary examination concentrates on determining whether anomalies such as hypospadias, chordee, cryptorchidism, micropallus, and ambiguous genitalia are present. These external anomalies may be associated with internal anomalies involving the upper urinary tract as well. The anus is examined for evidence of tags, its placement, and its patency.

The back should be assessed, especially for the shape of the spine and any associated defects, such as myelomeningocele. These defects prompt further radiologic evaluation to assess for potential functional limitations. In addition, a sacral dimple or hair tuft at

• **Fig. 19.2** Canthal Measurements. Various eye measurements are depicted (top). A indicates the outer canthal distance, B indicates the inner canthal distance, and C indicates the interpupillary distance (IPD), which is difficult to measure directly. The IPD can be determined using the graph at the bottom or with the Pryor formula: $IPD = (A - B) 2 + B$. (From Feingold M, Bossert WH. Normal values for selected physical parameters: an aid to syndrome delineation. *Birth Defects Orig Artic Ser.* 1974;10:1–16.)

the base of the spine should be noted, because either could signify developmental abnormalities in the underlying neural tissue.

Minor anomalies are often manifested in the extremities. Gross differences in the hands and feet include polydactyly (more than five digits), and whether the extra digits are located in a preaxial (first digit) or postaxial (fifth digit) position should be noted. Syndactyly (fusion of the digits), clinodactyly (incurving of the digits), and hand and foot lengths, which should be expressed as a percentile measured on age-appropriate graphs (Figs. 19.8–19.9), are important to document. Often these data can provide important clues to a unifying syndrome.

Dermal ridge patterns, or dermatoglyphics, are formed on the palms and soles early in embryonic life, and they vary considerably among individuals. This variation can be inherited and can be influenced by disturbances to the development of the peripheral limb buds. Environmental exposures and chromosomal aberrations can greatly affect the formation of these structures and are reflected

• **Fig. 19.3** A Nomogram for Interpupillary Distance at Different Ages for Both Sexes. (From Feingold M, Bossert WH. Normal values for selected physical parameters: an aid to syndrome delineation. *Birth Defects Orig Artic Ser.* 1974;10:1–16.)

• **Fig. 19.4** A graph of palpebral fissure length from birth to age 16 years for both sexes. (From Hall JG, Allanson JE, Gripp KW, Slavotinek A. *Handbook of Physical Measurements.* New York, NY: Oxford University Press; 2007.)

by the dermatoglyphic pattern of an individual. Each of the distal phalanges has one of three basic dermal ridge patterns: arches, whorls, or loops (Fig. 19.10). The predominance of a single pattern can be an associated feature of a genetic disorder. For example, the occurrence of arches on eight or more digits is a rare event but is frequently encountered in children with trisomy 18 (Table 19.2).

Deltas, or triradii, form at the convergence of three sets of ridges on the palm. This junction is where the hypothenar, thenar, and distal palmar patterns converge. There are typically no triradii in the hypothenar area of the palm, but when patterning is present or is large, a distal triradius arises, which is found in only 4% of normal Caucasian individuals but in 85% of patients with trisomy

• **Fig. 19.5** Ear Placement. Using the medial canthi (A and B) as landmarks, one draws a central horizontal line and extends it to a point (C) on the side of the face. Ears attached below this line are considered low set.

• **Fig. 19.6** Graph showing various percentiles for ear length plotted against age. (From Feingold M, Bossert WH. Normal values for selected physical parameters: an aid to syndrome delineation. *Birth Defects Orig Artic Ser.* 1974;10:1–16.)

• **Fig. 19.7** The internipple distance as a percentage of the chest circumference plotted against age for both sexes. (From Feingold M, Bossert WH. Normal values for selected physical parameters: an aid to syndrome delineation. *Birth Defects Orig Artic Ser.* 1974;10:1–16.)

TABLE 19.2 Dermatoglyphic Patterns Associated With Specific Dysmorphic Disorders

| Dermatoglyphic Pattern | Associated Disorders |
|------------------------|--|
| Excess arches | Trisomy 13, trisomy 18, Klinefelter syndrome (47,XXY), deletion 5p (cri du chat), fetal phenytoin exposure |
| Excess ulnar loops | Trisomy 21 |
| Excess whorls | Smith–Lemli–Opitz syndrome, Turner syndrome (45,X), 18q deletion |

21 (Down syndrome). A single transverse palmar crease is found in 4% of controls but in more than half of patients with trisomy 21 (Fig. 19.11) and in even greater proportions in patients with other trisomies. The hallual area of the foot, located at the base of the big toe, also has a dermal ridge pattern, usually a loop or whorl. A simple pattern or open field in this region is found in less than 1% of controls but in more than 50% of patients with Down syndrome (Fig. 19.12). This unusual dermal pattern is also associated with hypoplasia of the hallual pad and a wide space between the great and second toes in these patients.

An examination of the skin is also important, since phakomatoses or skin manifestations can herald the presence of an underlying disorder (Smithson and Winter, 2004). Examples are café-au-lait spots (associated with neurofibromatosis type I) and ash leaf spots (associated with tuberous sclerosis and detected with the use of a Wood lamp). Irregular pigmentation can be suggestive of

chromosomal mosaicism, in which the different skin pigmentation patterns represent a different, mixed chromosomal composition. Hemangiomas and other skin diseases are also noteworthy.

Finally, a careful neurologic examination with input from a specialist is often warranted in the child with multiple anomalies, because the neurologic status is often the most reliable prognostic indicator. Evaluation of tone, feeding, unusual movements, and the presence of seizure activity are critical pieces of diagnostic information.

Adjunct Studies

An exhaustive physical examination often reveals differences that require further evaluation for diagnostic, prognostic, and treatment

purposes (Box 19.4). Poor feeding or cyanosis may lead to detection of internal organ malformations on echocardiogram or abdominal ultrasonography. Differences in head shape suggest the need for skull radiographs, three-dimensional computed tomography, or magnetic resonance imaging (MRI) of the brain. A disproportionality of the limbs prompts a skeletal survey and bone age measurement.

• BOX 19.5 Underlying Mechanisms of Malformation

Syndrome

Pathogenetically related pattern of anomalies

Sequence

Pattern of anomalies derived from a presumed or known previous anomaly or mechanical disturbance

Association

Nonrandom occurrence of multiple anomalies

Field Defect

Disturbance of a developmental field leading to a pattern of anomalies

It is prudent in children with anomalies involving multiple systems to obtain the input of relevant specialists. This step is often essential to medical decision making and for planning interventions. Abnormal neurologic findings should prompt a consultation with a trained specialist and interpretation of studies such as head ultrasonography, brain MRI, brainstem auditory evoked responses, and electroencephalogram for seizure activity. Muscle dysfunction might result in the ordering of electromyography, muscle ultrasound, or nerve conduction studies. Visual involvement requires a fundoscopic examination by an experienced pediatric ophthalmologist, and sometimes studies of visual evoked responses or electroretinograms are needed to predict visual prognosis. Often there are well-characterized genetic disorders that have a specific pattern of abnormal findings in these highly specialized studies. Even when a unifying diagnosis is reached, there is often variation in the clinical phenotype, and determining the patient's prognosis on a system-by-system basis is typically the most appropriate and accurate way to proceed.

Literature Review

The occurrence of malformations can fit into one of several categories (Box 19.5). The next step toward reaching a diagnosis is to analyze the data generated from the evaluation and attempt to categorize the findings. A syndrome is a “collection of anomalies involving more than one developmental region or organ system” (Aase, 1990). The word itself means a “running together” or “pattern of multiple anomalies thought to be pathogenetically related.” Therefore a given congenital anomaly may be an isolated defect in an otherwise normal individual or part of a multiple malformation syndrome. Furthermore, the primary malformation itself can determine additional defects through an interrelated cascade of physical and functional processes; if ensuing malformations are related to one primary defect, factor, or event, a pathogenetic sequence has occurred. A classic example is the Pierre Robin sequence or constellation, consisting of a small recessed jaw, midline U-shaped cleft palate, and relatively large and protruding tongue. The primary anomaly is the small jaw, which does not allow adequate room for the tongue and displaces it superiorly. The displaced tongue prevents closure of the palatine shelves, causing the cleft palate. The recurrence risk with this isolated occurrence is negligible. However, one should also remember that such sequences can also be part of a larger constellation of findings that does fit into a syndrome, as Pierre Robin sequence can when it is part of the recurrent 22q11.2 deletion syndrome or Stickler syndrome (associated with mutations in one of several collagen genes). The recurrence

risk for an affected individual passing on these particular syndromes to their children is 50% (autosomal dominant inheritance).

In addition, a cluster of several malformations that are not developmentally related can occur in a nonrandom fashion called an *association* that may appear without characteristic dysmorphic features. One such statistically nonrandom association of defects consists of *vertebral defects*, *anal atresia*, *cardiac defects*, *tracheo-esophageal fistula*, *esophageal atresia*, *renal dysplasia*, and *limb anomalies* (VACTERL). It should be noted that not all features need to be present and that the extent of involvement of each system is widely variable. Although there have been various candidate genes and chromosomal regions described in some patients with VACTERL association, there is no common genetic etiology known at this time (Chen et al., 2016). CHARGE syndrome (*coloboma*, *heart disease*, *atresia choanae*, *retarded growth and development*, *genital anomalies*, and *ear anomalies/deafness*) was considered an association until the *CHD7* gene was identified to cause approximately 60%–70% of the cases (Lalani et al., 2006). Additionally, pathogenic variants in the *SEMA3E* gene have been described in a small number of patients (Lalani et al., 2004).

These associations often manifest as sporadic rather than familial occurrences. Because they are not clearly related by a common etiology or pathogenesis, associations are not considered syndromes and do not technically constitute a diagnosis. Instead, they are a recognition of a statistically significant association of features. It is important to remember that many of these same anomalies can occur as features of chromosomal aneuploidy or other syndromes. Syndromic malformations tend to occur in more than one developmental field. A field defect or complex is a set of primary malformations in a developmental field that originates from a single or primary abnormality in embryonic development (see Box 19.5).

When generating a differential diagnosis of malformations that might occur together, the evaluator must also consider structures that may appear abnormally formed but in fact are structures that underwent normal development and then received some insult that distorted their true form (Box 19.6). For example, a *deformation* describes the abnormal form, shape, or position of a part of the body that was caused by mechanical forces. Examples are clubfoot, hip dislocation, and craniofacial asymmetry; they can result from intrinsic (embryonic) or extrinsic (intrauterine) mechanical forces that alter the shape or position of an organ or part that had already undergone normal differentiation. Deformations are estimated to occur in 2% of births, and such factors as fetal crowding from

the presence of multiple fetuses and uterine malformations, as well as oligohydramnios, and a face presentation during delivery can cause them.

Along similar lines, a *disruption* describes a “morphologic defect of an organ, part of an organ, or larger region of the body resulting from the extrinsic breakdown of, or an interference with, an originally normal developmental process” (Aase, 1990). The classic example of a disruption is entanglement of the fetus in amniotic bands. Amniotic bands are ribbons of amnion that have ruptured in utero and cause disruptions of normal developmental processes in the fetus, either through physical blockage or interruption of the blood supply or by entangling and tearing of developing structures. This effect is seen most often with digits and limbs, and remnants of the bands, or constriction marks, can frequently be seen at birth. If the fetus should swallow a band, a cleft palate might result; this etiology is a very different etiology from that of cleft palate occurring as a primary malformation. Recurrence risk counseling of the parent would be very different in these two scenarios.

Dysplasias occur when there is “an abnormal organization of cells into tissue(s) and its morphologic results” (Aase, 1990). Dysplasia tends to be tissue specific rather than organ specific (e.g., skeletal dysplasia) and can be localized or generalized.

In summary, structural or morphologic changes identified at birth can occur during intrauterine development as a result of malformations, deformations, disruptions, or dysplasia. However, approximately 90% of deformations undergo spontaneous correction. Malformations and disruptions often require surgical intervention when possible. Dysplasias are typically not correctable, and the affected individual experiences the clinical effects of the underlying cell or tissue abnormality for life (Table 19.3).

After the history and physical evaluation are complete, a cross-reference of two or more anomalies is useful to generate a differential diagnosis. When the rest of the neonate’s physical and history findings are added, the possibilities can often be narrowed down to a few entities that may be amenable to diagnostic testing. If multiple anomalies are present, it is usually best to start with the least common. As Aase (1990) has stated, “The best clues are the rarest. The physical features that will be the most helpful on differential diagnosis are those infrequently seen either in isolation or as part of syndromes. Quite often, these are not the most obvious anomalies or even the ones that have the greatest significance for the patient’s health.” Cross-referencing is usually best accomplished by using published compendia of malformation syndromes. These compendia have been supplemented by databases that are accessible online (i.e., GeneReviews, Online Mendelian Inheritance in Man, PubMed, Simulconsult, Phenomizer, etc.). The availability of such tools allows the cross-referenced features to be compared easily with those of other described syndromes that may include similar

malformations. This systematic review produces a differential diagnosis for the constellation of features described and identifies references to pertinent literature.

The recognition of patterns of genetic entities involves the comparison of the proband with the examiner's personal experience of known cases and a search of the literature. Multiple anomalies may be causally related, occur together in a statistically associated basis, or occur together merely by chance. Diagnosis of a genetic disorder relies heavily on the ability of the clinician to suspect, detect, and correctly interpret physical and developmental findings and to recognize specific patterns. Accurate diagnosis of a syndrome in a child is important to the identification of major complications and their treatment if possible. It is also crucial for long-term management of patients and for parental counseling about recurrence in future offspring.

Specialized Laboratory Tests

In sorting through the multiple possibilities listed, the geneticist uses one other important tool – the availability of highly specialized cytogenetic and molecular genetic testing, including:

- Karyotype
- Fluorescence in situ hybridization
- Chromosomal microarray (see Chapter 20)
- Molecular analysis, such as sequencing (single gene, panel, exome, genome), methylation testing (e.g., for Beckwith–Wiedemann, Prader–Willi, or Angelman syndromes), or polymerase chain reaction–based techniques (e.g., for congenital myotonic dystrophy or fragile X syndrome)

The standard karyotype, or analysis of stretched and stained chromosome preparations usually taken from a peripheral blood sample, can often confirm a suggested diagnosis or explain a set of major malformations not classically encountered together. Further description of specific chromosomal abnormalities is addressed in Chapter 20; it is sufficient to note that multiple malformation syndromes can result from large visible chromosome rearrangements that lead to deletion or addition of genetic material (aneuploidy). These rearrangements can involve an entire arm of a chromosome or can be submicroscopic, requiring further special testing. It has become the standard of care in several centers to offer more specialized molecular testing, such as a chromosome microarray, as an adjunct to or instead of karyotype analysis. In general, microarray-based methods are currently focused on detecting copy number changes (smaller deletions or duplications not detectable by a karyotype) and can be performed in a targeted or genome-wide fashion (Emanuel and Saitta, 2007). Individual gene sequencing or next-generation sequencing of gene panels, an exome (sequencing of the exons of the genes), or a genome (sequencing the entirety of an individual's genetic makeup) can also be performed. It can be useful to inquire with a geneticist or genetic counselor for the availability of specific gene mutation testing that may be clinically available or performed on a research basis. GeneTests and the Genetic Testing Registry are Internet databases of laboratories

worldwide that provide such services (<https://www.genetests.org>; <https://www.ncbi.nlm.nih.gov/gtr/>).

Diagnosis

There are cases in which, after a detailed examination, exhaustive literature search, and genetic testing, no unifying diagnosis is evident. Aase (1990), a dysmorphologist, advises, “Don't panic! The absence of a diagnosis may be distressing to the diagnostician and the family, but it is much less dangerous than the possibility of assigning the wrong diagnosis with the risk of erroneous genetic and prognostic counseling and possibly hazardous treatment.” Therefore in cases in which there is no clear diagnosis, prognosis and treatment should be determined according to the organ systems involved and the extent of their impairment. In addition, when the newborn has a severe, untreatable impairment or the patient's condition is critical, it may be prudent to offer and obtain consent for a full postmortem examination by an experienced pediatric pathologist. A skin sample, and sometimes blood, can be taken from the expired fetus (or newborn prior to death) for establishing a cell line or for extracting DNA for future testing. Information gained from such investigations may often become relevant for family members, including the parents, allowing one to provide accurate recurrence risk counseling and perhaps offer prenatal testing of a new pregnancy. Such information can often help to provide closure for the family as well.

When should a genetics evaluation be considered? The following clinical situations prompt a further genetic evaluation and counseling by a specialist:

- Multiple anatomic anomalies
- History of maternal exposure to teratogens
- Familial disorders
- Increased carrier frequency or ethnic risk
- Multiple pregnancy losses

As described previously, if a birth defect is identified in the presenting patient or proband, especially if the defect is associated with other anatomic anomalies, short stature, or developmental delays, the features of a specific genetic syndrome may be present. A known history of maternal exposure to a potential teratogen would also be an indication for consultation. Conditions appearing to be familial, a family history of hereditary disorders involving malformation of a major organ, or major physical differences such as unusual body proportions, short stature, or irregular skin pigmentation would warrant genetic investigation. Mental retardation, blindness, hearing loss, or neurologic deterioration in multiple family members suggests a genetic etiology. Likewise, a strong family history of cancer or a defined ethnic risk for specific disorders such as Ashkenazi Jewish heritage and its association with a higher carrier frequency for Tay–Sachs disease would be an indication for genetic evaluation. The occurrence of multiple pregnancy losses would also raise the suspicion of a genetically influenced cause and indicate the need for further investigation and counseling.

Summary

Diseases with underlying genetic bases have significant effects on health care and its delivery. An appreciation of these entities, coupled with an organized, systematic evaluation, can help to define the

nature of a given disorder and aid in the development of the optimal plan of treatment and care for the patient.

Chromosome Disorders

CHAD R. HALDEMAN-ENGLERT, SULAGNA C. SAITTA, AND ELAINE H. ZACKAI

KEY POINTS

- Early identification of the genetic nature of a given condition in a patient can aid in treatment and help to identify resources for providing better health care to these individuals.
- In counseling the family of a newborn in whom Down syndrome has been diagnosed, it is important to include the organ systems affected in the baby and the severity of each malformation when one is defining a prognosis. The wide variability of the phenotype should be emphasized, with a care plan tailored to the needs of the individual patient.
- Although the prognosis in trisomy 13 and trisomy 18 is extremely poor, there is emerging evidence that various interventions can improve the survival and quality of life for the child and the family, and this should be discussed with the parents during a prenatal or postnatal visit.
- The use of chromosomal microarrays allows the identification of smaller chromosomal deletions and duplications that are largely undetectable by standard karyotyping techniques and should be considered in the genetic evaluation of a newborn with multiple congenital anomalies.
- Noninvasive prenatal screening is a relatively new technology that analyzes the cell-free fetal (placental) DNA fraction circulating in maternal peripheral blood. This testing is accepted as an initial screen for select aneuploidy conditions, and if an abnormality is identified, then diagnostic testing such as karyotyping or chromosomal microarray analysis of amniotic cells is recommended.

It has been estimated that 3% of newborns have a major structural anomaly that will affect their quality of life. Although most of these patients have a single malformation, 0.7% of infants have multiple major anatomic malformations. In an additional 2%, a major anomaly is discovered by the age of 5 years. Early identification of the genetic nature of a given condition can aid in treatment and help to identify resources for providing better health care to these individuals. This chapter will focus on genetic disorders and syndromes with underlying chromosomal abnormalities that typically manifest themselves in the newborn period. In addition, it will discuss the shift in genetic evaluation and diagnosis toward the use of microarray-based and next generation sequencing diagnostic techniques.

Human Karyotype

Chromosomes consist of tightly compacted DNA whose structure is maintained by association with histones and other proteins.

When treated and stretched, chromosomes from dividing cells can be visualized under the light microscope as linear structures with two arms joined by a centromere. The short arm is designated the *p arm* and the long arm is designated the *q arm*. The ends of the *p* and *q* arms are known as *telomeres*. Human chromosomes were first visualized in 1956 (Lejeune and Turpin, 1960), and each pair shows a distinctive size, centromeric position, and staining or banding pattern after treatment with special dyes, allowing it to be identified and classified. In standard international cytogenetic nomenclature, each chromosome is identified by a number, in general from largest to smallest. This presentation, or karyotype (Fig. 20.1), normally consists of 46 chromosomes, with 22 pairs of autosomes and one set of sex chromosomes – two X chromosomes for females (46,XX) and an X chromosome and a Y chromosome for males (46,XY).

Karyotype analysis is performed in cells undergoing mitosis, or cell division, in which the chromosomes condense and can be stained and visualized. Thus cells that can be stimulated to divide and grow in culture, such as peripheral blood lymphocytes, skin fibroblasts, and amniocytes, are typically used. Cells from bone marrow and chorionic villi are normally undergoing rapid cell division and can also be karyotyped successfully. Historically, several different staining methods have been described. However, G-banding (Giemsa staining) is the standard cytogenetic method used. This technique permits a resolution of at least 400 bands among all the chromosomes and can be adapted to allow high-resolution analysis of up to 800 bands to analyze structural rearrangements as small as 5–10 million base pairs or 5–10 megabase (Mb) pairs.

Gamete formation, either spermatogenesis or oogenesis, is accomplished by a process known as *meiosis*. In the first part of meiosis (meiosis I), homologous chromosomes align as pairs and cross over, exchanging genetic material, also known as *recombination*. In this stage, reduction division, the recombined pairs separate and the typical diploid content (46 chromosomes) of the cell is reduced by half to a haploid complement of 23 chromosomes. In the next stage, meiosis II, the chromosomes separate, similar to mitosis (Nussbaum et al., 2007). The full diploid state of the cell will be restored at the time of fertilization.

An imbalance of genetic material, or aneuploidy, occurs from a net loss or gain of genetic material during sperm or egg formation or less commonly during the initial divisions of the embryo. This missing or extra genetic material can be small pieces or parts of chromosomes or an entire chromosome itself. The classic recognizable aneuploidy syndromes involve trisomy (three copies of a full chromosome) such as those of chromosomes 13, 18, and 21 or monosomy (only a single copy) of a complete chromosome, such

• **Fig. 20.1** G-Banded Human Male Karyotype. The 46 chromosomes are arranged in 23 pairs, each with a specific banding pattern.

as the X chromosome. Trisomies in particular can occur from nondisjunction, a failure of normal chromosome separation. In such cases, a pair of homologs does not separate in meiosis, and one daughter cell receives both homologs of that pair, and the other cell receives none. This event can occur in either stage of gamete division, meiosis I or meiosis II. Most human meiotic nondisjunction arises during oocyte formation, specifically in maternal meiosis I. Nondisjunction of meiosis I is especially pronounced in trisomies of the acrocentric chromosomes (13, 14, 15, 21, and 22) and in XXX trisomy (MacDonald et al., 1994;

Zaragoza et al., 1994). The occurrence of meiotic nondisjunction increases significantly with maternal age. Therefore prenatal karyotyping from amniocentesis or chorionic villus sampling (CVS) is offered to women aged 35 years or older (Hook and Cross, 1982). Noninvasive prenatal screening is a relatively new technology that analyzes the cell-free fetal DNA fraction circulating in maternal peripheral blood. This screen uses sequencing-based approaches to assess the copy number of specific chromosomes. It is commonly being performed as an initial screen for select aneuploidy conditions. If there is a high risk of a chromosomal abnormality in the fetus,

diagnostic testing such as karyotyping or chromosomal microarray analysis of amniotic cells is recommended (Hardisty and Vora, 2014).

Nondisjunction can also occur in mitosis, with uneven division of genetic material during early embryonic cell division. This can result in two cell lines: one trisomic lineage that is potentially viable and one monosomic line. If this event occurs after the first postzygotic division, cells with a normal chromosome complement may also exist with cells containing an aneuploid complement, as a *mosaic* chromosome constitution. This could be a possible mechanism for the occurrence of mosaic Down syndrome, where a certain percentage of the cells in the patient have three chromosomes 21, while the rest of the cells have the expected chromosome complement containing two chromosomes 21. Mosaicism is also seen with sex chromosome aneuploidies, most notably mosaic Turner syndrome, where a subset of the cells examined show a 45,X complement and another population of cells from the patient may have a normal 46,XX or XY complement.

Partial aneuploidy may result from several mechanisms, such as rearrangements of material between nonhomologous chromosomes that can occur in the gametes of a balanced translocation carrier. The carrier parent has no net loss or gain of genetic material and is usually phenotypically normal; however, the offspring are at increased risk of an unbalanced rearrangement and its phenotypic consequences. Attention has also been focused on deletion syndromes caused by the loss of genetic material from several chromosomes (e.g., 1p-, 4p-, 5p-), with a resulting, often recognizable, phenotype. Other chromosome microdeletions have been mechanistically tied to aberrant recombination due to the presence of segmental duplications, or large “blocks” or segments of DNA that contain chromosome-specific repetitive sequences (Emanuel and Shaikh, 2001). The highly homologous repeats can mediate misalignment and nonallelic homologous recombination between two homologs. Segmental duplications are present in regions of the genome prone to rearrangements, such as the pericentromeric regions of 7q11, 15q11, 17q11, and 22q11, leading to the phenotypes seen in Williams–Beuren syndrome, Prader–Willi or Angelman syndrome, Charcot–Marie–Tooth disease or hereditary neuropathy with liability to pressure palsies, and the recurrent 22q11.2 deletion syndromes, respectively (Emanuel and Saitta, 2007). The use of chromosomal microarrays has allowed the identification of smaller chromosomal rearrangements (deletions and duplications) that are submicroscopic and largely unrecognized by standard karyotyping techniques. The use of high-resolution microarrays in infants with multiple congenital anomalies has, in many cases, led to the identification of a specific genotype, with clinical investigations then further defining the associated phenotype (Bejani and Shaffer, 2008).

Trisomies

Down Syndrome (Trisomy 21)

Lejeune and Turpin (1960) demonstrated that trisomy of human chromosome 21 caused the constellation of findings recognized as Down syndrome (Fig. 20.2). This chromosome disorder was the first to be described and is the most common viable autosomal trisomy, occurring in approximately 1 in 700–800 live births (Hook, 1992). The vast majority (>90%) occur secondary to meiotic nondisjunction, and a pronounced maternal age effect is encountered. Approximately 3%–5% of cases are caused by a translocation that could be either *de novo* or inherited from a balanced translocation-carrier parent that subsequently becomes unbalanced and trisomic in the baby. Typically, the translocated chromosome 21 rearranges with another acrocentric chromosome, often chromosome 14, resulting in a Robertsonian translocation. Mitotic nondisjunction, or mosaic Down syndrome, has been demonstrated in approximately 3% of cases as well, with variable features ranging from normal to a typical Down syndrome phenotype.

Clinical Features

It is the more common occurrence of Down syndrome in babies of older mothers that led to the recommendation for prenatal karyotyping for advanced maternal age (>35 years) at the time of conception, with samples typically obtained by amniocentesis after 15 weeks' gestation, or CVS at 10–12 weeks' gestation. Maternal serum analyte testing is recommended for prenatal screening purposes for all pregnant women, with results showing low alpha fetoprotein, low unconjugated estriol, and elevated total human chorionic gonadotropin levels. Noninvasive prenatal screening is also accepted as an initial study for fetal aneuploidy (Committee Opinion 640, 2015). Associated ultrasonographic findings for Down syndrome, including a cardiac defect, shortened long bones, underdeveloped fetal nasal bone, nuchal translucency or thickening, echogenic small bowel, and duodenal atresia (“double-bubble” sign), may be seen in 50%–60% of fetuses.

Most patients with Down syndrome, if it is not diagnosed prenatally, are usually recognized at birth because of the typical phenotypic features. The constellation of physical findings associated with Down syndrome consists of brachycephaly, the presence of a third or confluent fontanel, upward-slanted palpebral fissures, epicanthal folds, Brushfield spots in the irises, flattened nasal root, small posteriorly rotated ears with overfolded superior helices, prominent tongue, short neck with excess nuchal skin, single palmar creases, brachydactyly, fifth-finger clinodactyly, exaggerated gap between the first and second toes, open field hallux pattern, and

• **Fig. 20.2** Newborn with Down syndrome (trisomy 21) illustrating some of the characteristic facial features, including upward-slanting palpebral fissures and a flat facial profile.

hypotonia (see Fig. 20.2). Often the physical features conform to an easily distinguishable phenotype, but in some cases prematurity or ethnic variations can make a clinical diagnosis less straightforward. An immediate karyotype is indicated to confirm the diagnosis and its mechanism (e.g. trisomy, translocation) and as preparation for recurrence risk counseling for the family. Malformations involving many organ systems have been described in Down syndrome, and whether the diagnosis is known prenatally or determined in the newborn period, several clinical investigations are warranted when this diagnosis is suggested (Bull, 2011). The most common malformation is congenital heart disease (seen in approximately 50% of cases), which may require surgical intervention. Atrioventricular canal defects are often encountered (mean of 40%), although ventricular septal defects (VSDs), atrial septal defects (ASDs), tetralogy of Fallot, and patent ductus arteriosus (PDA) are all described in the disorder. An echocardiogram is indicated in all cases, and medical and surgical interventions for cardiac lesions are routine. Gastrointestinal malformations, especially duodenal atresia (2%–5%), in addition to Hirschsprung disease and less frequently encountered conditions, such as esophageal atresias, fistulas, and webs throughout the tract, have been described. It is critical to carefully monitor the baby's feeding and bowel function before considering discharge from the nursery.

Although growth parameters can be in the range of 10%–25% at birth, significantly decreased postnatal growth velocity is encountered in these patients. Separate growth curves have been devised for patients with Down syndrome (Fernandes et al., 2001), because growth retardation involving height, weight, and head circumference has been well documented. However, the most recent health supervision guidelines for patients with Down syndrome recommend that patients be assessed on the basis of the World Health Organization or Centers for Disease Control and Prevention growth curves (Bull, 2011). An initial ophthalmologic evaluation is also indicated in the first few months of life and then annually, because strabismus, cataracts, myopia, and glaucoma have been shown to be more common in children with Down syndrome. In addition, hearing loss of heterogenous origin is present in approximately half of patients, with middle ear disease contributing to this problem.

Spinal cord compression caused by atlantoaxial subluxation from ligamentous laxity and subsequent neurologic sequelae can be a complication of the disorder. Radiographs are obtained when there is concern for myopathic symptoms related to spinal cord compression (weakness, abnormal reflexes, incontinence, etc.). Physicians should be vigilant in evaluating the cervical spine, especially before administration of anesthesia. Other associated disorders that merit screening are hypothyroidism in approximately 5% of patients, often with the presence of thyroid autoantibodies. Initial evaluation occurs with newborn screening programs, followed by additional measurement of thyroid-stimulating hormone and free thyroxine levels at 6 months, 12 months, and then yearly thereafter. Bone marrow dyscrasias, such as neonatal thrombocytopenia, and transient self-resolving myeloproliferative disorders, such as leukemoid reaction, have been observed in the first year of life, and a complete blood count with differential should be performed at birth. An elevated rate of leukemia with a relative risk 10–18 times greater than normal up to age 16 years has been described. Acute nonlymphoblastic leukemia is seen at higher rates in congenital or newborn cases, but the distribution becomes similar to that of non-Down syndrome patients after age 3 years. Survival of patients with Down syndrome is shorter after a diagnosis of acute lymphoblastic leukemia than in diploid patients (Epstein,

2001). There is also an increased risk of iron-deficiency anemia, with recommended screening to include annual hemoglobin level measurement starting at 12 months of age then annually thereafter. If the hemoglobin level is low, then a complete blood count with iron studies should be performed.

Patients with Down syndrome demonstrate a wide range of developmental abilities, with highly variable personalities and behavioral phenotypes as well (Pueschel et al., 1991). Central hypotonia with concomitant motor delay is most pronounced in the first 3 years of life, as are language delays. Therefore immediate and intensive early intervention and developmental therapy are critical for maximizing the developmental outcome. A wide range of intelligence has been described, with conflicting data on genetic and environmental modifiers of outcome (Epstein, 2001). Seizure disorders occur in 5%–10% of patients, often manifesting themselves in infancy.

The most common causes of death in patients with Down syndrome are related to congenital heart disease, to infection (e.g., pneumonia) that is thought to be associated with defects in T-cell maturation and function, and to malignancy (Fong and Brodeur, 1987). Once medical and surgical interventions for the correction of associated congenital malformations are complete and successful, the long-term survival rate is good. However, less than half of patients survive to 60 years, and less than 15% survive past 68 years. Neurodegenerative disease with features of Alzheimer disease is encountered in most patients who are older than 40 years. The gene for amyloid precursor protein (*APP*) is on chromosome 21, and overexpression of this gene in the trisomic state leads to early-onset beta-amyloid plaques in the brain. Neurofibrillary tangles, cerebrovascular pathology, white matter pathology, oxidative damage, neuroinflammation, and neuron loss are also seen in the brains of patients with Down syndrome. Frank dementia is not typical, as there appear to be compensatory responses that delay the onset of dementia after the development of amyloid deposition (Head et al., 2016). Men with Down syndrome are almost always infertile, whereas small numbers of affected women have reproduced (Epstein, 2001).

In counseling the family of a newborn in whom Down syndrome has been diagnosed, it is important to include the organ systems affected in the baby and the severity of each malformation when one is defining a prognosis. Above all, the wide variability of the phenotype should be emphasized, with a care plan tailored to the needs of the individual patient.

Genetic Counseling

If a complete (full chromosome) or mosaic trisomy 21 is found, parental karyotypes are generally not analyzed, because the karyotypes are normal in virtually all cases. After having one child with Down syndrome, a mother's recurrence risk for another affected child is approximately 1% higher than her age-specific risk (Hook, 1992). This fact is especially significant in younger mothers, whose age-specific risks are low. If a de novo translocation resulting in Down syndrome is found, the recurrence risk is less than 1%. If the mother is found to carry a constitutional balanced Robertsonian translocation, the risk of another translocation Down syndrome fetus is approximately 15% at the gestational age when amniocentesis is offered and 10% at birth. However, if the father is the translocation carrier, the recurrence risk is significantly smaller, approximately 1%–2% (Epstein, 2001). Whereas array-based diagnostic techniques will identify the copy number change associated with the trisomy, structural rearrangements such as Robertsonian translocations are not readily detected. In this situation a karyotype will provide

information regarding the mechanism of the copy number change, which is needed for accurate recurrence risk counseling.

Trisomy 18 (Edwards Syndrome)

Trisomy 18 is encountered in 1 in 6000 live births and is associated with a high rate of intrauterine demise. It is estimated that only 5% of conceptuses with trisomy 18 survive to birth and that 30% of fetuses in whom trisomy 18 is diagnosed by second-trimester amniocentesis die before the end of the pregnancy (Hook, 1992). Findings on prenatal ultrasonography can raise suspicion for the disorder – growth retardation, oligohydramnios or polyhydramnios, heart defects, myelomeningocele, clenched fists, and limb anomalies. Diagnostic testing is recommended when prenatal ultrasonography findings are suggestive of this condition. Maternal serum screening can show low values for alpha fetoprotein, unconjugated estradiol, and total human chorionic gonadotropin.

Clinical Features

Phenotypic features present at birth consist of intrauterine growth restriction (1500–2500 g at term), small narrow cranium with prominent occiput, open metopic suture, low-set posteriorly rotated ears, and micrognathia with small mouth. Characteristic clenched hands with overlapping digits, excess of arches on dermatoglyphic examination, hypoplastic nails, and “rocker-bottom” feet or prominent heels with convex soles (Fig. 20.3) are also described. Additional malformations encountered in this syndrome include congenital heart disease (ASD, VSD, PDA, pulmonic stenosis, aortic coarctation), cleft palate, clubfoot deformity, renal malformations, brain anomalies, choanal atresia, eye malformations, vertebral anomalies, hypospadias, cryptorchidism, and limb defects, especially of the radial rays.

The prognosis in this disorder is extremely poor, with more than 90% of babies succumbing in the first 6 months of life and only 5% alive at 1 year old. Death is caused by central apnea, infection, and congestive heart failure. The newborn period is characterized by poor feeding and growth, typically requiring tube feedings. Universal poor growth and profound mental retardation

• **Fig. 20.3** Newborn with trisomy 18, showing prominent occiput, characteristic facial appearance, and clenched hands.

with developmental progress typically leveling at that of a 6-month-old infant (Baty et al., 1994) have been documented. Malignant tumors such as hepatoblastoma and Wilms tumor have been described in some survivors. There is emerging evidence that various interventions can improve the survival and quality of life for the child and the family, and this should be discussed with the parents during a prenatal or postnatal visit (Carey, 2012; Kosho and Carey, 2016).

Genetic Counseling

The typical estimate of the recurrence risk for trisomy 18 in a future pregnancy is a 1% risk over the maternal age-specific risk for any viable autosomal trisomy (Hook, 1992). Trisomy occurring from a structural rearrangement, such as a translocation, warrants parental karyotype analysis before the recurrence risk can be assessed.

Trisomy 13 (Patau Syndrome)

It has been estimated that approximately 2%–3% of fetuses with trisomy 13 survive to birth, with a frequency of 1 in 12,500 to 1 in 21,000 live births (Hook, 1992). As with other trisomies, abnormal noninvasive prenatal screening findings for advanced maternal age or the presence of fetal ultrasonographic findings may prompt diagnostic testing by CVS or amniocentesis that can result in a prenatal diagnosis of trisomy 13.

Clinical Features

Trisomy 13–associated midline malformations include congenital heart disease, cleft palate, holoprosencephaly, renal anomalies, and postaxial polydactyly (Fig. 20.4). In addition, microcephaly, eye

• **Fig. 20.4** Stillborn With Trisomy 13. The facial appearance is that of cebocephaly, which is associated with holoprosencephaly. There is an extra digit on the ulnar border of the right hand.

anomalies, and scalp defects can suggest the diagnosis. Brain malformations such as holoprosencephaly are found in more than half of patients with concomitant seizure disorders. Microcephaly, split sutures, and open fontanelles are encountered. A scalp defect (cutis aplasia) that has sometimes been mistakenly attributed to a fetal scalp monitor is specific to the disorder, being found in 50% of cases. Eye malformations, including iris colobomas and hamartomatous cartilage “islands,” can be seen on fundoscopic examination.

Congenital heart disease is present in approximately 80% of patients, usually VSD, ASD, PDA, or dextrocardia. Limb anomalies, such as postaxial polydactyly, single palmar creases, and hyperconvex narrow fingernails, are also seen. The fingers can be flexed or overlapped and can show camptodactyly. An increased frequency of nuclear projections in neutrophils, giving a drumstick appearance similar to that of Barr bodies, can also be found. This finding would be especially striking in males, in whom Barr bodies would not be expected.

As with trisomy 18, prognosis for the fetus with trisomy 13 is extremely poor, with 80% mortality in the neonatal period and less than 5% of patients surviving to 6 months old. Mental retardation is profound, and many patients are blind and deaf as well. Feeding difficulties are typical. Also similar to trisomy 18, various interventions can increase the survival of these infants and improve their overall quality of life. A discussion with the parents should be considered regarding these possibilities (Carey, 2012; Kosho and Carey, 2016).

Genetic Counseling

Recurrence risk data suggest that, as with trisomy 18, the chance that a woman will have a child with any trisomy after a pregnancy affected by trisomy 13 is rare. The estimated risk is 1% higher than the maternal age–related risk for the recurrence of any viable autosomal trisomy in a subsequent pregnancy.

45,X (Turner Syndrome)

In early embryogenesis, two active X chromosomes are required for normal development. Turner syndrome, a phenotype associated with loss of all or part of one copy of the X chromosome in a female conceptus, occurs in approximately 1 in 2500 female newborns. The 45,X karyotype or loss of one entire X chromosome accounts for approximately half of the cases. A variety of X chromosome anomalies—including deletions, isochromosomes, ring chromosomes, and translocations—account for the remainder of the causes. It is important to note that approximately 0.1% of fetuses with a 45,X complement survive to term; the vast majority (>99%) are spontaneously aborted. This fact underscores the requirement for both X chromosomes during embryonic development. Additional studies indicate that in approximately 80% of cases, it is the paternally derived X chromosome that is lost (Willard et al., 2001).

Clinical Features

There is wide phenotypic variability in patients with Turner syndrome. Features present at birth include short stature, webbed neck, craniofacial differences (epicanthal folds and high arched palate), hearing loss, shield chest, renal anomalies, lymphedema of the hands and feet with nail hypoplasia, and congenital heart disease. Typical cardiac defects include bicuspid aortic valve, coarctation of the aorta, valvular aortic stenosis, and mitral valve prolapse.

Growth issues, especially short stature, are the predominant concern in childhood and adolescence; the mean adult height of patients with Turner syndrome is 135–150 cm without treatment. Growth hormone therapy has been shown to increase final adult height, with the age of initiation of therapy not yet established, but it can be administered as early as 9 months (Bondy, 2007). Primary ovarian failure caused by gonadal dysplasia (streak gonads) can result in delay of secondary sexual characteristics and primary amenorrhea. Cyclic hormonal therapy should reflect the process of normal puberty (Bondy, 2007) to aid the development of secondary sex characteristics and menses as well as to help bone mass. Infertility, related to gonadal dysplasia, is typical and has been successfully treated with assisted reproduction techniques and donor oocytes. It is important to evaluate the patient for structural cardiovascular defects before pregnancy.

In terms of intellectual development, specific difficulties with spatial and perceptual thinking lead to a lower performance intelligence quotient; however, this syndrome is not characterized by mental retardation.

Triploidy (69,XXX or 69,XXY)

As its name implies, triploidy is a karyotype containing three copies of each chromosome. The mechanisms that lead to this state include fertilization of the egg by two different sperm (dispermy) and complete failure of normal chromosome separation in maternal meiosis. The vast majority of triploid fetuses are spontaneously aborted, accounting for up to 15% of chromosomally abnormal pregnancy losses. Live births of affected fetuses are rare, and reports of survival beyond infancy are only anecdotal. Mosaicism with combinations of diploid and triploid cells (mixoploid) has also been documented. Malformations, including hydrocephalus, neural tube defects, ocular and auricular malformations, cardiac defects, and 3–4 syndactyly of the fingers, are associated findings. In addition, the placenta is often abnormal, typically large, and cystic.

Deletion Syndromes

In addition to the aneuploid conditions described previously, partial monosomy of a chromosome can lead to a recognizable pattern of malformation. Three well-described syndromes that are associated with the deletion or loss of genetic material from the short, or p, arms of chromosomes 1, 4, and 5 are described. All these syndromes are associated with heterozygous deletions that involve the loss of many genes located in a specific region, or haploinsufficiency.

Chromosome 1p Deletion Syndrome (1p–)

Monosomy for the distal short arm of chromosome 1, or deletion of 1p36, has been associated with a constellation of clinical findings. A characteristic facies consisting of frontal bossing, large anterior fontanel, flattened midface with deep-set eyes, and developmental delay has been described (Fig. 20.5). Orofacial clefting, hypotonia, seizures, deafness, and cardiomyopathy are also noted.

This deletion syndrome is estimated to occur in approximately 1 in 10,000 live births, and it is the most frequently occurring subtelomeric deletion. Greater recognition of the phenotype and widespread use of chromosomal microarrays has led to improved diagnosis of this condition. Most deletions arise *de novo* in the patient, with approximately 3% being attributable to malsegregation of a balanced parental translocation. The size of the deletion differs, from submicroscopic (<5 Mb) to large, cytogenetically visible

• Fig. 20.5 Child with deletion of 1p.

deletions larger than 30 Mb. A correlation between the size of the deletion and the severity of clinical features is suggested.

Wolf–Hirschhorn Syndrome (4p–)

Distal deletions of the short arm of chromosome 4 are associated with a recognizable pattern of malformation. This syndrome is estimated to occur in 1 in 50,000 births and has features such as intrauterine growth restriction, microcephaly, midline structural defects such as cleft lip and cleft palate, cardiac septal defects, and hypospadias. The characteristic facial features are described as the *Greek helmet* facies, as evidenced by hypertelorism with epicanthi, a high forehead with a prominent glabella, and a beaked nose. Prominent, low-set ears are also seen. Hypotonia, failure to thrive, and developmental delay are common, with approximately 30% mortality in the first year of life. Many patients have lived well into childhood and even into adulthood, although profound growth impairment and mental retardation are typical and often accompanied by seizures.

The 4p deletions are typically cytogenetically visible on karyotype analysis, although small submicroscopic deletions have also been described. In cases where the clinical features are suggestive but the karyotype is not revealing, further cytogenetic analysis using specific 4p telomere fluorescence in situ hybridization (FISH) probes or more commonly a chromosomal microarray can be diagnostic. Microarray analysis also provides information about the relative size and gene content of the deleted region. More than 80% of 4p deletions arise de novo in the patient, with minimal risk of recurrence. In the 10%–15% of cases resulting from a translocation, analysis of parental samples clinically is indicated for appropriate recurrence risk counseling.

Cri du Chat Syndrome (5p–)

Partial monosomy of 5p is seen in approximately 1 in 50,000 live births and is associated with a multiple congenital anomaly syndrome

named for the unusual cry of the affected babies, described as similar to that of a cat, or *cri du chat*. The constellation of features associated with this disorder includes low birth weight, microcephaly, round face, hypertelorism or telecanthus, downward-slanting palpebral fissures, epicanthi, and broad nasal bridge. Hypotonia and cardiac defects are also seen, including ASD, VSD, and tetralogy of Fallot. Early issues include failure to thrive and pronounced developmental delay. The unusual cry usually resolves during infancy, and survival into adulthood is possible but is typically associated with severe mental retardation. Intensive therapy appears to provide some benefit, and more sensitive measures of cognition demonstrate clearly better receptive language skills than expressive language ability. Therefore children may understand more complex verbal language than their expressive skills might demonstrate (Cornish et al., 1999).

It is estimated that almost 100 genes are lost when the putative critical region from 5p15.2 to p15.33 is deleted (Shaffer et al., 2001; Zhang et al., 2005). Close to 90% of 5p deletions arise de novo in the affected child, incurring a minimal risk of recurrence (<1%). The remainder arise from malsegregation of a balanced translocation in a carrier parent, which would be associated with a 10%–15% risk of recurrence of an unbalanced karyotype in a future liveborn infant. Parental chromosome analysis is indicated for proper recurrence risk counseling.

Chromosomal Microarrays

In the past 10 years, characterization of variations of the genome that fall in the range between the single nucleotide and visible chromosomal changes—submicroscopic structural variants (typically less than 5 Mb) that cannot be seen by standard karyotyping—has been accomplished through the use of chromosomal microarrays (Bejjani and Shaffer, 2008; Miller et al., 2010; Martin and Warburton, 2015). Microarray-based methods are focused on detecting copy number changes, such as gains and losses of chromosomal material; however, structural rearrangements such as balanced

translocations or inversions are not detectable by this method. Microarray testing can be performed in either a targeted or more commonly a genome-wide fashion. Single nucleotide polymorphism arrays include probes based on known polymorphisms present in the human genome. Single nucleotide polymorphism-based arrays or dense oligonucleotide arrays have the advantage of detecting gains or losses of shorter stretches of the genome, because the probes for a given region can be densely arrayed, and the sensitivity for detecting alterations of that region is greatly enhanced. With a single test, microarrays can detect copy number variants in a genome-wide approach, revealing disorders usually identified by cytogenetic analysis and multiple individual FISH studies. Whereas microarray analysis can provide a robust and exceptional level of resolution from a diagnostic perspective, the major difficulty with the current interpretation of the results lies in assigning causality and clinical significance to the multiple alterations that are detected in each individual. Toward this end, the use of online databases (e.g., Database of Genomic Variants, <http://dgv.tcag.ca/dgv/app/home>) with information on normal variation in multiple ethnic populations and testing of unaffected parents remain standard approaches for discerning whether a copy number change is likely to cause disease.

Segmental Duplications and Microdeletion Syndromes

A greater appreciation of the complexity of the human genome and its structure has been afforded with the completion of the human genome sequence. This work has focused attention on regions of the genome that are prone to rearrangement. The presence of these regions appears to have a significant role in the origin of several genetic disorders (Emanuel and Shaikh, 2001; Emanuel and Saitta, 2007). These disorders result from inappropriate dosage of crucial genes in a given genomic segment via either structural mechanisms (deletion or duplication) or functional mechanisms (imprinting or uniparental disomy [UPD]). It has also been demonstrated that many of the regions prone to recurrent rearrangements have a common element: the presence of large, chromosome-specific segmental duplications. These repeat structures appear to mediate misalignment and aberrant crossover during recombination, resulting in rearrangements such as deletions and duplications (Fig. 20.6). Many of these large low copy repeat structures are localized to a single chromosome or within a single chromosomal band. Examples of such genomic disorders include hemophilia A (inversion of Xq28), Sotos syndrome (in which a number of patients have a deletion of 5q35), Smith–Magenis syndrome (deletion of 17p11.2), Charcot–Marie–Tooth disease (interstitial duplication on 17p12), and the reciprocal deletion of this same region of 17p12, leading to hereditary neuropathy with liability to pressure palsies, and a small percentage of patients with neurofibromatosis type I (deletion involving 17q11.2).

In this section we highlight several deletion syndromes that occur on chromosomes whose underlying genomic structure contains segmental duplications. These include Williams–Beuren syndrome (involving 7q11.2), Prader–Willi syndrome (PWS) or Angelman syndrome (involving an imprinted region of 15q11 through 15q13), and the recurrent 22q11.2 microdeletion syndrome (also known as DiGeorge or velocardiofacial syndrome). The latter is the most commonly occurring microdeletion syndrome in humans. It is important to note that in several of these microdeletion syndromes, reciprocal duplications of the exact same region may also occur

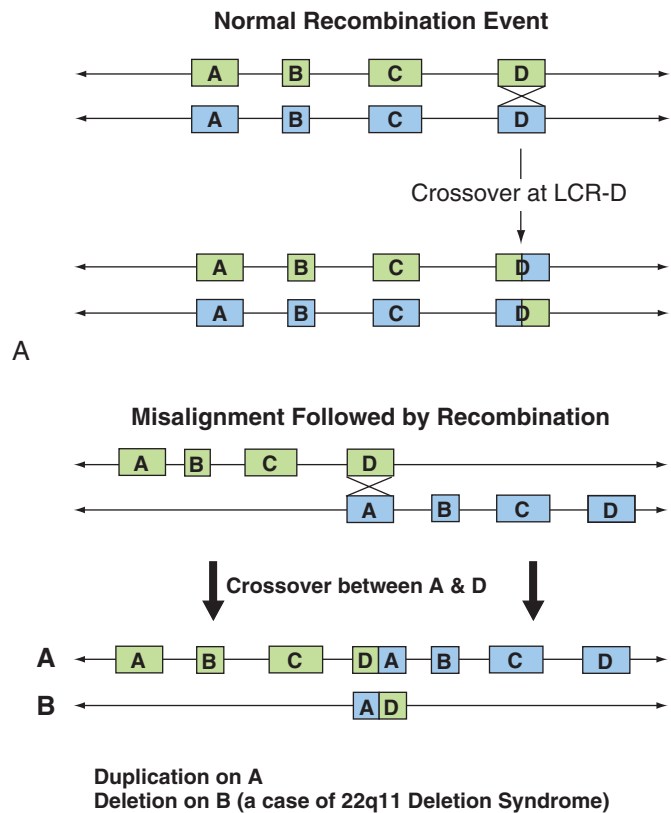

Fig. 20.6 (A) Alignment of low copy repeats before exchange. (B) Misalignment of low copy repeats before exchange can result in rearrangement. LCR, Low copy repeats.

(see Fig. 20.6) and can show a different phenotype than the deletion of the same region. In general, duplication syndromes cause fewer abnormalities and show a wider phenotypic variability, but they are often characterized by developmental delays with or without behavioral abnormalities.

Newly recognized recurrent microdeletion syndromes (e.g., 1q21.1, 3q29, 15q13.3, 16p11.2, and 17q21) were identified because of the increased use of chromosomal microarrays in the clinical and research settings. These regions are similarly flanked by segmental duplications, likely predisposing to their rearrangements. Many of the patients with these particular rearrangements do not receive a clinical diagnosis in the newborn period, since they may not present with significant anatomic malformations or dysmorphic features that prompt a genetic evaluation; however, they can present during childhood with variable clinical findings. Typically there is developmental delay, behavioral abnormalities (such as an autism spectrum disorder), or intellectual disability. Many of these syndromes are complicated because they have also been reported in unaffected family members, which proves to be a challenge when one is ascribing causality to the rearrangement.

When an abnormality is identified by microarray analysis, the genes located in the affected region can be identified. It is then possible to decide what role, if any, the affected genes have in the observed phenotype. For example, deleted genes could be identified that may predispose a patient to cancer because of a germline loss of one copy of a tumor suppressor gene (Adams et al., 2009), prompting careful surveillance for tumor formation. Therefore a genetic paradigm has developed where patients are initially

genotyped (genotype first), followed by evaluation of the altered genes in a given region to determine their possible effect on the future phenotype.

Williams–Beuren Syndrome (7q11.2 Deletion)

The estimated incidence of Williams–Beuren syndrome is 1 in 10,000 live births. The phenotype has a variable spectrum but usually consists of distinctive facies, growth and developmental retardation, cardiovascular anomalies, and occasionally infantile hypercalcemia (Fig. 20.7). Babies with Williams–Beuren syndrome usually show some degree of intrauterine growth restriction with mild microcephaly. Facial features include epicanthal folds with

periorbital fullness of subcutaneous tissues, flat midface, anteverted nostrils, long philtrum, thick lips, large open mouth, and stellate irises that may not be discernible at birth. Most infants have a cardiovascular abnormality; supraventricular aortic stenosis (SVAS) is the most commonly associated defect, seen in more than 50% of cases. Pulmonary artery stenosis is also often encountered. It is interesting to note that isolated SVAS can also exist as a separate autosomal dominant trait and has been shown to occur from mutations of the elastin gene (*ELN*), which is located within the deletion region on 7q11.2. Patients with Williams–Beuren syndrome are typically missing one copy of the elastin gene.

Hypercalcemia, which is manifested in approximately 10% of patients with this disorder, is severe and persists through infancy.

• **Fig. 20.7** Williams–Beuren Syndrome. (A) Neonate with a coarse face, periorbital fullness, wide mouth, and thick lips with decreased Cupid's bow. (B) Neonate profile showing periorbital fullness, flat nasal bridge with full tip, and prominent cheeks. (C) Infant with periorbital fullness, flat nasal bridge, thick lips with decreased Cupid's bow, pouty lower lip, and low-set, full cheeks. (D) Infant profile showing dolichocephaly (increased anteroposterior diameter of head), a higher nasal bridge than in the neonate, full nasal tip, pouty lower lip, long neck, sloping shoulders, and part of pectus excavatum.

Umbilical and inguinal hernias are also associated features. Issues in infancy include feeding and growth problems, with pronounced irritability and colicky behavior. Hoarse voice, strabismus, hypertension, and joint mobility restrictions may develop later in childhood. In terms of development, the typical mild to moderate mental retardation can be masked by relatively advanced language skills, although gross motor and visual–motor integration skills are especially affected. Attention-deficit disorders are common, and a characteristic outgoing personality is often described in affected children.

Many of the classic features of Williams–Beuren syndrome are not clearly discernible in the newborn period, but the diagnosis should be suggested in any child with SVAS, hypercalcemia, and facial features consistent with the disorder. The diagnosis can be confirmed quickly by chromosomal microarray analysis or FISH using probes specific for the deleted region of 7q11.2. Because the condition is typically sporadic and most deletions arise *de novo*, the risk of recurrence in subsequent pregnancies is minimal. An affected adult, however, would pass on the condition in an autosomal dominant manner, with a 50% risk of the disorder in his or her child.

22q11.2 Deletion Syndrome

A deletion of 22q11.2 has been identified in most patients with the classically termed conditions DiGeorge, velocardiofacial, and conotruncal anomaly face syndromes, leading to the realization that these clinical entities all reflect features of the same genomic disorder (McDonald-McGinn *et al.*, 2015). The list of findings associated with 22q11.2 deletion syndrome is extensive and differs by patient. Estimates indicate that 22q11.2 microdeletion syndrome occurs in approximately 1 in 1000 fetuses (Grati *et al.*, 2015). This disorder is the most common microdeletion syndrome occurring in humans and is a significant health concern in the general population.

The phenotype is characterized by a conotruncal cardiac anomaly and often aplasia or hypoplasia of the thymus and parathyroid glands. Most patients with a deletion can receive a diagnosis as newborns or infants with significant cardiovascular malformations,

including interrupted aortic arch type B, truncus arteriosus, or tetralogy of Fallot, along with functional T-cell abnormalities and hypocalcemia. In addition, facial dysmorphism may be present (Fig. 20.8), including hooded eyelids, hypertelorism, overfolded ears, bulbous nasal tip, a small mouth, and micrognathia. Since the initial report by DiGeorge in 1968, the spectrum of associated clinical features has been expanded to include anomalies such as palatal anomalies, vascular rings, feeding and swallowing problems, gastroesophageal reflux, renal agenesis, and hypospadias (McDonald-McGinn *et al.*, 1997). Before advances in the medical and surgical treatment of children with complex congenital cardiac disease and immune deficiencies, this disorder was associated with significant morbidity and mortality.

Developmental delays or learning disabilities have been reported in most patients with 22q11.2 deletion syndrome, and a wide range of developmental and behavioral findings have been observed in young children (Emanuel *et al.*, 2001). In the preschool years, affected children were most commonly found to be hypotonic and developmentally delayed with language and speech difficulties. Severe or profound retardation was not seen, and one-third of patients functioned within the average range (Bassett *et al.*, 2011).

The vast majority of patients (80%–90%) have the same large deletion, approximately 2.4–3 Mb, that is detected by FISH (Fig. 20.9) or chromosomal microarray. The deletion affects approximately 50 genes and 7 micro ribonucleic acids (McDonald-McGinn *et al.*, 2015). The size of the deletion remains unchanged when it is inherited from an affected parent. However, the phenotype can be widely variable, even within a family. Although smaller recurrent deletions that are half the size of the common deletion occur (1.5 Mb), a smaller size does not correspond to milder symptoms, making genotype–phenotype correlations difficult.

Most 22q11 deletions occur as *de novo* events, with less than 10% of them being inherited from an affected parent. The prevalence of these *de novo* 22q11.2 deletions indicates a high rearrangement rate within this genomic region that is related to the presence of recombination-permissive duplicated DNA sequences or segmental duplications in 22q11 (Emanuel and Shaikh, 2001; Emanuel and Saitta, 2007; Shaikh *et al.*, 2007).

• **Fig. 20.8** Facial differences associated with 22q deletion syndrome. A. Frontal view showing upslanting palpebral fissures, bulbous nose, and small chin. B. Profile view showing deep set eyes and overfolded superior helices.

• **Fig. 20.9** Fluorescence in situ hybridization study of a 22q deletion. The white arrows point to both copies of the 22nd chromosome. One chromosome 22 shows a hybridization pattern involving a control probe (green) and the 22q11.2 region probe (red). The other chromosome 22 shows a hybridization pattern of a control probe (green) and absent 22q11.2 region probe (probe), suggesting this region is deleted. (Courtesy of Beverly S. Emanuel.)

Additional Microdeletion and Microduplication Syndromes

As mentioned previously, several identified genetic syndromes have been described with the increased use of chromosomal microarrays (Slavotinek, 2008; Watson et al., 2014). These regions are frequently flanked by segmental duplications, which is the likely reason for their prevalence in diverse patient populations, as well as the fact that there are reciprocal rearrangements (deletion or duplication). Almost all of the patients with these more recently recognized deletions or duplications were not initially recognized on the basis of their clinical features but were instead ascertained by microarray analysis.

Deletions of 1q21.1 with a size of approximately 1.35 Mb have been seen in patients with variable presentations, including developmental and behavioral abnormalities, mild facial dysmorphism, and microcephaly (Brunetti-Pierri et al., 2008; Mefford et al., 2008). In 3q29 microdeletion syndrome, the deletion is approximately 1.6 Mb and was initially discovered (Willatt et al., 2005) in patients with mild to moderate mental retardation, microcephaly, and nonspecific facial dysmorphism. Duplications of this region have also been described in patients with developmental delays, mental retardation, and microcephaly (Lisi et al., 2008). Reciprocal duplications of the region deleted in Williams–Beuren syndrome (7q11.23) are characterized by distinctive facial features, congenital anomalies, and intellectual and developmental disabilities including poor expressive speech in contrast to the deletion of the same region (Mervis et al., 2015). The 15q13.3 region is distal to the more commonly known 15q11–q13 locus associated with Prader–Willi and Angelman syndromes. Patients with a 1.5-Mb deletion of 15q13.3 have variable phenotypes but typically manifest seizures or abnormal electroencephalograms (Sharp et al., 2008). A smaller

680-kilobase (kb) deletion has also been described in a range of patients with neurobehavioral phenotypes (Shinawi et al., 2009). Interestingly, this deletion is often maternally inherited, suggesting that there might be an imprinting mechanism involved. Deletions of 16p12.2 can manifest as developmental and intellectual disability, cardiac malformations, epilepsy, hearing loss, renal and genital anomalies (the latter in males), and cleft lip/palate (Girirajan et al., 2015). A recurrent 550-kb deletion of 16p11.2 has been discovered in approximately 1% of patients with autism (Weiss et al., 2008) and the reciprocal duplication associated with attention deficit–hyperactivity disorder and schizophrenia (McCarthy et al., 2009; Shinawi et al., 2010). Chromosome deletions of 17q21.31 of approximately 500–650 kb were also found in patients with developmental delays, learning disabilities, and variable facial dysmorphism. Mutations of *KANSL1*, located within the 17q21.31 deletion, can also be associated with the same phenotype (Koolen and de Vries, 2013).

Disorders of Imprinted Chromosomes

A growing recognition of mechanisms regulating gene expression has emerged in the last few decades. Two of the most exciting concepts with important clinical correlates are imprinting and UPD. The term *genomic imprinting* implies that a whole region of a chromosome or a group of genes in a given region is subject to a difference in their expression that depends on whether they reside on the maternally inherited or the paternally inherited chromosome. In these cases, a genetic disorder might manifest itself on the basis of whether the genomic region was inherited maternally or paternally. The genes in an imprinted region are not necessarily mutated, but they are epigenetically marked such that the cell can distinguish between the maternal and paternal copies and coordinate expression on the basis of that distinction. At the molecular level, it appears that differences in the methylation of the DNA, and its replication and regulation at the transcriptional level, appear to be involved in this mechanism. This mechanism has become an area of important research advancement, and there are now more than 200 known or predicted genes and chromosomal regions thought to be important in human disease (<http://www.geneimprint.com/site/genes-by-species>).

Prader–Willi Syndrome

It has been demonstrated that occasionally, instead of one copy of each chromosome being inherited from each parent, both copies of a given chromosome or chromosomal region can come from the same parent. This phenomenon, known as *uniparental disomy* or *UPD*, is associated with advanced maternal age. It becomes a significant issue when the chromosome involved is imprinted or has regions on it that are imprinted.

PWS involves the loss of activity from the paternally derived proximal long arm of chromosome 15 (15q11). This loss can occur through deletion or disruption of this region or through maternal UPD such that no paternal chromosome 15 is present (Nicholls et al., 1989). Newborns with PWS have pronounced central hypotonia, hyporeflexia, and a weak cry. The poor tone manifests itself as sucking and swallowing difficulties that can lead to failure to thrive and the need for feeding tubes in infancy. Facial differences that have been described include bifrontal narrowing, almond-shaped eyes, and a small, downturned mouth. Genitalia are often hypoplastic, with cryptorchidism being common in boys with this syndrome. The commonly reported small hands and feet are not

always demonstrated in the newborn. Strabismus and hypopigmentation relative to the family are also common.

A history of poor fetal activity during the pregnancy can often be elicited, especially if the mother has had prior pregnancies. Consistent with the hypotonia, breech presentation and perinatal insults are found more frequently than usual. The extreme hypotonia begins to abate in the first year of life, and motor development improves, although developmental delay is the rule, especially for gross motor skills and speech. The feeding improves in the first few years of life and gives way to often uncontrollable hyperphagia and obesity. This issue and other behavioral problems, including severe temper tantrums, obsessive–compulsive disorder, and autism spectrum disorders, are encountered throughout life. Most patients manifest mild to moderate mental retardation. Early diagnosis and recognition of the various medical issues along with preemptive implementation of behavioral therapy are essential components of the optimal management of these issues.

Deletions of the region critical in PWS have been demonstrated in up to 70% of patients. The deletion can be detected by a chromosomal microarray or FISH analysis using a probe specific for this region of chromosome 15. A small number of patients have a disruption of this area as the result of a chromosomal translocation. To date, no single gene in this region has been implicated as the cause, but five genes are known to have paternal-only expression of protein-encoding genes (*MKRN3*, *MAGEL2*, *NECDIN*, *SNURF*, and *SNRPN*). It has been noted, however, that patients who have PWS as a result of a deletion of the region are more likely to be hypopigmented. This feature has been attributed to deletion of a gene involved in pigmentation, *OCA2* (Rinchik et al., 1993). Recurrence risks are negligible in cases in which de novo deletions are found and sporadic occurrence is usually encountered.

Approximately 20%–25% of patients with PWS show maternal UPD that can be detected by means of a molecular assay designed to assess specific methylation differences between maternal and paternal alleles. Methylation analysis findings are abnormal in more than 99% of affected individuals but will not determine whether the cause is a deletion or maternal UPD. Further study is required if an abnormal methylation result is obtained. A maternal age effect has been demonstrated in UPD cases, and recurrence risks in families without deletions are estimated at 1 in 1000. In addition, this region of the genome is subject to regulation by imprinting. Large chromosome-specific segmental duplications are found in 15q11 and have been implicated in mediating the recurrent deletion of this genomic region (reviewed in Emanuel and Shaikh, 2001; Emanuel and Saitta, 2007).

Angelman Syndrome

Loss of genetic material from the 15q11 region from the maternal copy of chromosome 15 is associated with Angelman syndrome. Clinical features are not evident in the newborn period and infancy but include significant mental retardation, seizures, ataxic gait, tongue thrusting, inappropriate bursts of laughter, and facial differences, including protruding jaw, wide mouth, thin upper lip, and widely spaced teeth. The mental retardation and hypopigmentation overlap with the features of PWS but Angelman syndrome is a distinct entity.

Seventy percent to 75% of patients have a deletion of 15q11 that is detectable by FISH analysis. A small percentage (3%–5%) have evidence of paternal isodisomy (two paternal copies) of this region of chromosome 15, with no apparent maternal chromosome contribution. Unlike PWS, Angelman syndrome has been associated

with mutations in a single gene, *UBE3A* (which encodes an enzyme involved in the ubiquitin pathway of protein degradation), that has been detected in up to 10% of patients. In addition, mutations of an imprinting center locus on chromosome 15 are associated with 1%–2% of Angelman phenotypes (Dagli et al., 2015). Methylation analysis can be performed and will detect abnormalities in approximately 75%–80% of patients because of a deletion or UPD. If methylation analysis findings are normal but Angelman syndrome is still suspected, *UBE3A* sequence analysis should be considered. The vast majority of cases result from a sporadic event, and the risk of recurrence can be best evaluated once the genetic mechanism has been determined for a given patient.

Beckwith–Wiedemann Syndrome

Beckwith–Wiedemann syndrome affects approximately 1 in 14,000 newborns and manifests itself as an overgrowth syndrome in the neonatal period. The characteristic findings are macrosomia, abdominal wall defect, and macroglossia (Fig. 20.10). Affected babies are large for their gestational age with proportionate length and weight. Infants of mothers with diabetes also manifest macrosomia but are more likely to have a weight disproportionately greater than length. Advanced bone age is also noted in Beckwith–Wiedemann syndrome. Hemihypertrophy caused by asymmetric growth is common, as is visceromegaly of various organs, including the spleen, kidneys, liver, pancreas, and adrenal glands.

Other characteristic features of the syndrome are macroglossia, linear creases of the earlobe with indentations on the posterior helix, and severe hypoglycemia. Although the hypoglycemia responds quickly to therapy, it can be present for several months; therefore recognition of the condition and immediate therapeutic intervention are critical in these cases. The hypoglycemia resolves spontaneously with age, and the physical diagnostic features also become less prominent with age, making the diagnosis more difficult to ascertain.

Equally important is the establishment of routine ultrasonographic surveillance at regular intervals, because children with Beckwith–Wiedemann syndrome are at increased risk of malignant tumors, especially Wilms tumor. The estimated risk is as high as 8% for patients with hemihypertrophy. Many centers currently perform ultrasonography at 3-month intervals until the school-age years (approximately 8 years old). Monitoring of serum alpha fetoprotein levels at the same intervals until age 4 years has proved

• **Fig. 20.10** Macrosomic Infant With Macroglossia and Lax Abdominal Musculature. These findings are typical of Beckwith–Wiedemann syndrome. (From Viljoen DL, Jaquire Z, Woods DL. Prenatal diagnosis in autosomal dominant Beckwith–Wiedemann syndrome. *Prenat Diagn.* 1991;11:167–175.)

valuable, as several cases of hepatoblastoma have also been reported and detected with this adjunct study.

Although most cases of Beckwith–Wiedemann syndrome appear to arise de novo, up to 15% may be familial. In familial cases, the transmission is autosomal dominant, because of mutations of the *CDKN1C* gene in 40% of familial cases but only in 5%–10% of de novo cases. In addition, this region of the genome (11p15.5) appears to be imprinted such that the maternal allele is not usually expressed. The insulin-like growth factor type 2 gene (*IGF2*) is located in this region and encodes an important factor involved in fetal growth. Mutations causing overexpression of the paternal allele or underexpression of the maternal allele can result in an imbalance of expression leading to the overgrowth and tumor formation encountered in these patients. Paternal UPD has proved to be a mechanism involved in 10%–20% of sporadic cases of Beckwith–Wiedemann syndrome. A method for detecting methylation abnormalities at two distinct genetic loci within 11p15 accounts for approximately 60% of patients and is related to the overexpression of the *IGF2* gene. Therefore all the available testing methods combined can detect the cause in approximately 85% of patients with Beckwith–Wiedemann syndrome. The recurrence risk for future affected siblings or offspring of the proband depends on the specific genetic abnormality causing the disorder and can range from low (UPD, methylation abnormality) to as high as 50% (*CDKN1C* mutation).

Russell–Silver Syndrome

Russell–Silver syndrome presents in neonates with intrauterine growth retardation followed by postnatal growth deficiency. The

head size is usually normal, causing a relative macrocephaly that may have the appearance of hydrocephalus. Facial features can include a broad and prominent forehead, triangular-shaped face with a small chin, and downturned corners of the mouth. The fingers can show brachydactyly, camptodactyly, or more commonly fifth-finger clinodactyly. Other concerns involve limb-length discrepancy, delayed bone age, café au lait macules, hypospadias in males, developmental delays, diaphoresis, and hypoglycemia during the first 3 years of life. These patients are often examined by a geneticist as a toddler with growth retardation, proportionate short stature, and normal head circumference. When one is evaluating patients with growth retardation, it becomes important to know the prenatal and postnatal growth parameters, because they might provide a clue to the diagnosis of Russell–Silver syndrome.

The molecular mechanisms underlying the pathogenesis show that Russell–Silver syndrome is likely caused by abnormalities of imprinted genes. Maternal UPD of chromosome 7 is present in 7%–10% of patients, and the symptoms are likely caused by overexpression of the maternal *GRB10* gene, which suppresses the activity of various growth factor receptors. In approximately 35% of patients, imprinting abnormalities of 11p15.5 occur because of a loss of the paternally expressed *IGF2* gene, leading to decreased prenatal and postnatal growth. This finding contrasts with that for some patients with Beckwith–Wiedemann syndrome, in whom *IGF2* is overexpressed, causing increased growth. For that reason, patients with Russell–Silver syndrome do not have a significantly increased risk of neoplasia compared with patients with Beckwith–Wiedemann syndrome, and routine cancer surveillance protocols are typically not recommended.

Summary

This chapter has summarized the rapidly expanding field of chromosomal and genomic disorders, concentrating on those that commonly manifest themselves in the newborn period. The widespread development and clinical implementation of molecular cytogenetic techniques have allowed the identification of subtle rearrangements that were previously undetectable. These advances now enable the discernment of new syndromes in which the chromosomal anomaly may be defined before a characteristic phenotype is recognized. In addition, a greater understanding of

the role of segmental duplications and their effects on human genetic disorders as well as of the influence of mechanisms that regulate gene expression, such as imprinting, is emerging. The tremendous advances in genomics led by the completion of the Human Genome Project and the development of new molecular diagnostic tools present new challenges for clinicians to better diagnose, understand, and care for patients with genetic disorders and their families.

Introduction to Metabolic and Biochemical Genetic Diseases

STEPHEN CEDERBAUM

KEY POINTS

- Inborn errors may present in a variety of ways.
- Inborn errors should be systematically considered when one is evaluating an ill newborn.
- Inborn errors often present with unique or characteristic physical findings and also laboratory findings that help in developing a differential diagnosis.
- Newborn screening can be integrated into the evaluation of inborn errors.
- DNA sequencing can be used in the evaluation of sick infants.

Inborn errors of metabolism or biochemical genetic disorders are one type of genetic disease that may be encountered in the neonatal period as an acute or more indolent illness. In these disorders, a mutation in a gene leads to an absent or defective gene product or enzyme and results in the accumulation of the precursor of the enzyme or a byproduct of it, a shortage of the product of the enzymatic reaction, or a combination of both. In reality the effects of many inborn errors on normal physiology are much more profound, causing many changes in gene expression and normal biochemical function. One example is a case of propionic acidemia in which interference with the mitochondrial respiratory apparatus is rarely measured except by the ascertainment of an elevated blood lactate level, but that may be much more frequent and represent only the most obvious and easily measured alteration.

Inborn errors of metabolism may be inherited by any genetic mechanism—autosomal dominant, autosomal recessive, sex-linked recessive—or through a mutation in the independently inherited mitochondrial genome (mitochondrial DNA), which leads to a circumstance in which the mother alone passes the abnormal DNA to all of her children, but the affected or carrier father passes to none of his offspring.

Most inborn errors are inherited as autosomal recessive conditions, with the carrier parents rarely expressing any obvious metabolic phenotype. A small minority are inherited in a sex-linked recessive or codominant manner, and they will be discussed in the context of their particular disease. Examples include ornithine transcarbamylase

deficiency (a urea cycle disorder) and Fabry disease (a lysosomal storage disorder), the latter not appearing in the neonatal period.

When viewed from the perspective of disease mechanism, most genetic disorders, whether single-gene disorders or disorders involving imbalance of chromosomal materials, could be considered to be inborn errors of metabolism. One or more changes in the DNA result in either altered gene expression or expression of a mutated gene, which then leads secondarily to an altered product of the reaction or reactions. We will not use this expansive and grandiose interpretation of inborn errors but will rather confine ourselves to the more traditional definition described in the first paragraph. Thus disorders such as cystic fibrosis and spinal muscle atrophy, considered inborn errors that require broader interpretation, will not be considered.

The advent of newborn screening in the early part of the 1960s for phenylketonuria (PKU) established a new paradigm for approaching inborn errors of metabolism and making the diagnosis and treatment before the symptomatic presentation and hence preventing rather than treating the condition. This approach has proved to be remarkably successful for PKU and congenital hypothyroidism, with few patients becoming intellectually disabled. In subsequent years the menu of tests expanded gradually, but it has greatly expanded in the last decade with the implementation of expanded newborn screening using tandem mass spectrometry technology, which allows ascertainment of a constellation of disorders. This expanded testing should alter the probability of, and the diagnostic testing for, inborn errors when incorporated into the diagnostic algorithms of the ill newborn. Moreover, the advancing technology permits some of the newborn dried blood spot to be used for a wider palette of tests, some of which may already be available. The consequences of this expansion have a downside for the neonatologist and the neonatal intensive care unit staff members. For a variety of reasons the sick and premature newborn, usually receiving intravenous alimentation and having immature or damaged organs, is far more likely to have a false positive newborn screening test result and require follow-up testing. It is important to recognize that a number of traditionally tested diseases are outside this class of disorders, such as hypothyroidism, congenital adrenal hyperplasia, cystic fibrosis, and hemoglobinopathies.

When one is considering inborn errors of metabolism, it is important to consider the molecular basis of mutation. Large

deletions of a gene are certain to eliminate enzymatic function and any residual gene product. Smaller deletions, especially if they remove one or more of the in-phase coding triplets, may permit a stable protein to be made and to function to some extent. Most small deletions, however, cause the synthesis of unstable and out-of-phase proteins that do not function and that have a short half-life within the cell. Some single-base-change mutations can introduce a stop codon, causing the synthesis of the polypeptide to halt abruptly and leave a nonfunctional enzyme. Single-base changes introducing a new amino acid differ in their effects from complete loss of activity to a lesser impact and finally to having no effect whatsoever. When one considers that the mutation test is then all modulated through the unique genetic background of the individual, there is no single final phenotype, severity, or time of onset for any genetic disorder. This variation must be considered when any diagnosis, genetic or not genetic, is considered.

In the period since the publication of the previous edition of this book, DNA sequencing has become a much more accessible and affordable diagnostic modality, and it is likely to increase in relevance and use in the near-term future. When the diagnosis is established by biochemical criteria, mutation analysis, done electively, is likely to enhance our understanding of the disorder in an individual patient and help to guide therapy. When one is confronted with a more challenging and ambiguous patient, DNA testing in the form of whole exome or whole genome sequencing is likely to become the genetic diagnostic modality of choice.

Classification of Inborn Errors of Metabolism

Each professional uses classification systems to permit effective reasoning as to possible causes of a symptom complex. A system for understanding inborn errors of metabolism is shown in [Box 21.1](#). Each group has common characteristics, modes of presentation, types of molecules involved, and tests that would be applied. Because the demarcation between the groups is not sharp, other systems can see them differently. This discussion is restricted to those disorders that may be symptomatic in the newborn period or in early infancy, whereas many severe disorders would be unlikely to be associated with neonatal disease and will be given less emphasis.

• BOX 21.1 Classification of Inborn Errors of Metabolism, 2007

Small-molecule disorders

- Amino acids
- Organic acids
- Sugars

Lysosomal storage disorders

- Mucopolysaccharides
- Sphingolipids
- Glycolipids

Energy metabolism disorders

- Oxidation disorders
- Fatty acid mobilization and metabolism disorders
- Glycogen storage diseases

Peroxisomal and membrane biogenesis disorders

Carbohydrate-deficient glycoprotein disorders

Cholesterol biosynthetic disorders

Disorders of biogenic amines, folate, and pyridoxine

Transport disorders

Purine and pyrimidine metabolism disorders

Receptor disorders

The disorders more commonly seen in the neonatal period are listed in [Box 21.2](#).

The first group consists of newborns with progressive lethargy, poor suck, neurologic deterioration, and often death. They have inborn errors of amino acids, the urea cycle, organic acids, or sugar metabolism. This group of patients is the product of normal pregnancies and deliveries and becomes ill after 36 hours of life, when the maternal circulation no longer cleanses the accumulating small molecules from the fetal or newborn blood, and the offending metabolites accumulate in intoxicating amounts ([Box 21.3](#)). Examples include maple syrup urine disease, methylmalonic and propionic acidemias, galactosemia, and ornithine transcarbamylase deficiency. The general characteristics are given in [Box 21.4](#); they are the disorders for which expanded newborn screening may lead to earlier detection and a more rapid diagnosis. These patients' condition is most likely to resemble sepsis, and they should be treated with antibiotics. Most disorders manifesting themselves acutely in the newborn period will be detected by the newborn screen, with only some urea cycle disorders and lactic acidoses likely to be missed by this screening panel. When diagnosed, these conditions are treated with dialysis, limitation of protein intake (except for galactosemia), fluid, and caloric support and some specific interventions. The association of identifying physical and laboratory characteristics and various disorders is listed in [Tables 21.1–21.2](#). The individual disorders are discussed in Chapters 22 and 23. When a diagnosis of a metabolic disorder appears

• BOX 21.2 Common Types of Inborn Errors of Metabolism With Newborn Presentation

- Amino acid disorders
- Organic acid disorders
- Disorders of ammonia metabolism
- Disorders of carbohydrate metabolism
- Disorders of gluconeogenesis or hypoglycemia
- Disorders of fatty acid oxidation
- Primary lactic acidoses (respiratory chain defects)
- Disorders of vitamin or metal metabolism
- Storage diseases (infrequently)
- Peroxisomal disorders
- Disorders of sterol metabolism
- Congenital defects in glycosylation

• BOX 21.3 Metabolic Diseases With Newborn Coma Secondary to Toxic Metabolite Accumulation or Mitochondrial Failure

- Galactosemia
- Inborn errors of ammonia metabolism
- Maple syrup urine disease
- Nonketotic hyperglycinemia
- Methylmalonic acidemia with or without homocystinuria
- Propionic acidemia
- Isovaleric acidemia
- Multiple carboxylase deficiency
- Glutaric aciduria type 2
- Fatty acid oxidation defects
- Primary lactic acidosis
- Pyruvate dehydrogenase deficiency
- Pyruvate carboxylase deficiency
- Mitochondrial respiratory chain or electron transport chain defects

• BOX 21.4 Characteristics of Small-Molecule Disorders

- High levels of metabolites in body fluids
 - Normal physical phenotype
 - Neonatal presentation
 - Periods of stability and instability
 - Considered to be intoxication disorders
 - Can often be treated by external manipulation
- Lysosomal storage disorders
- Usually born normally
 - Course is progressive, relentless, and indolent
 - Deposition of material seen clinically and microscopically
 - May be deforming
 - Cannot be addressed exogenously by dietary means
- Disorders of energy metabolism
- Mixed presentation between the first two categories
 - Can be catastrophic at presentation
 - May be present at birth or develop later
 - Usually progressive
 - May cause malformations
 - May have episodes of deterioration
 - Usually not treatable by dietary means
 - May be tissue specific or preferential

likely, tests for plasma amino acids, urine organic acids, plasma acylcarnitine, and plasma carnitine should be repeated, and ammonia and lactate levels should be determined.

The second major category of inborn errors is the lysosomal storage diseases. This group of disorders results from defective function of a catabolic hydrolase located in the lysosome that is generally responsible for breaking down complex glycosaminoglycans and sphingolipids that are products of normal cellular turnover (see [Box 21.4](#)). Unlike the small-molecule disorders in which the metabolites are found freely circulating in the body fluid compartments, these compounds accumulate intracellularly, are not removed by the maternal circulation, and are present in limited amounts in the body fluids. They most often cause no apparent symptoms in the newborn period or early infancy, because the pathologic metabolites accumulate slowly with time. Exceptions to this finding are the severe form of α -glucosidase deficiency or Pompe disease, the neonatal form of α -galactosidase deficiency, or Krabbe disease and galactosialidosis. These findings are discussed in Chapter 23, and some are listed in [Table 21.1](#). The disorders of mucopolysaccharides and glycolipids lead to the characteristic features pejoratively and inappropriately referred to as *gargoylism*, which consist of an exaggerated eyebrow, coarse-appearing facies, thick skin, hirsutism, and multiple abnormalities of the bones and joints seen on a radiograph. Attention to the disorder is often drawn by the hepatosplenomegaly. The metabolites are synthesized in the body and are not influenced by dietary intake.

The third important category of metabolic disorders is insufficient generation of energy by the mitochondrial machinery. These disorders can be caused by the inability to provide substrates such as glucose in glycogenoses; the inability to deliver substrate to the site of oxidation, such as the fatty acid and carnitine transport disorders; the inability to break down fatty acids in a stepwise fashion to provide reduced flavin adenine dinucleotide to be oxidized; or the deficient function of the mitochondrial respiratory pathway and energy-generating system itself. These disorders have characteristics in between those of the acute, small-molecule disorders and the storage disorders (see [Box 21.4](#)). They differ

• BOX 21.5 Signs and Symptoms of Inborn Errors in the Newborn

- Neonatal catastrophe (life threatening)
- Poor suck and feeding
- Gastrointestinal problems, vomiting
- Respiratory distress
- Cardiac failure
- Neurologic abnormalities: alertness, tone, seizures
- Organomegaly
- Ocular abnormalities
- Cutaneous changes

• BOX 21.6 Metabolic Diseases With Congenital Malformations or Dysmorphic Features

- Cholesterol biosynthetic disorders
- Peroxisomal disorders
- Glutaric aciduria type 2
- Primary lactic acidoses
- Congenital defects in glycosylation
- Lysosomal storage disorders
- Menkes disease

from the small-molecule disorders in the possible onset immediately at birth or before and from storage disorders in the generally normal physical features with hepatomegaly alone, a regular feature of glycogen storage disorders. The small-molecule and energy-generating disorders are discussed in Chapter 22, and the lysosomal storage disorders are discussed in Chapter 23.

Of the remaining groups that are encountered less frequently, the peroxisomal biogenesis disorders, carbohydrate-deficient glycoprotein disorders, and Smith–Lemli–Opitz syndrome (a cholesterol biosynthetic disorder) are discussed in Chapter 23. Other disorders are too infrequent to be considered in a general neonatology textbook. Disorders of biogenic amines are discussed in Chapter 22 and in greater depth in Chapter 65 on neonatal seizures, along with consideration of pyridoxine and folate disorders.

Signs and Symptoms of Inborn Errors

The limited symptomatic repertoire of the sick newborn is well established, but it is worth repeating. For this reason, the first thought when one is confronting a newborn in a deteriorating condition, with lethargy, poor suck, temperature instability, and neurologic abnormalities, is sepsis ([Box 21.5](#)). Most metabolic specialists have never confronted a sick newborn who has not had a “septic work-up” and who is not receiving standard antibiotics. The issue then becomes when to perform a metabolic work-up. The standard answer is that it should be performed when the neonatologist is concerned that the newborn in extremis does not fit the pattern that is expected from a child with sepsis or hypoxia. That threshold will differ by individual. Negative results of tests for infectious agents, a nonconfirmatory white blood cell count, hypoglycemia, unexpectedly severe acidosis, or hyperammonemia could be important triggers. Although dysmorphic features are not characteristic of inborn errors, there are some that may have subtle or occasionally pronounced abnormality on a physical examination; they are listed in [Box 21.6](#) and [Table 21.2](#).

TABLE 21.1**Unique or Characteristic Physical Findings in Inborn Errors (Major Examples)**

| Finding | Error | Finding | Error |
|----------------------------------|--|---|--|
| Hepatomegaly | Galactosemia Glycogen storage diseases Gluconeogenic defects Disorders of fatty acid oxidation and transport Mitochondrial respiratory or electron transport chain defects Hereditary tyrosinemia type 1 Urea cycle defects Peroxisomal defects Niemann–Pick disease type C Congenital defects in glycosylation | Retinitis pigmentosa | Mitochondrial respiratory or electron transport chain defects Sjögren–Larsson syndrome Peroxisomal disorders Abetalipoproteinemia |
| Hepatosplenomegaly | Gangliosidoses Niemann–Pick disease type C Mucopolysaccharidoses Wolman disease Ceramidase deficiency | Optic atrophy or hypoplasia | Pyruvate dehydrogenase complex deficiency Mitochondrial disorders Leigh disease Peroxisomal disorders |
| Macrocephaly | Glutaric acidemia type 1 Canavan disease | Corneal clouding or opacities | Mucopolipidoses Mucopolysaccharidoses Steroid sulfatase deficiency |
| Microcephaly | Mitochondrial respiratory or electron transport chain defects Leigh disease Methylmalonic acidemia with homocystinuria | Cataracts | Galactosemia Lowe syndrome Mitochondrial respiratory or electron transport chain defects Peroxisomal disorders Congenital defects in glycosylation |
| Coarse facial features | Gangliosidosis Mucopolipidoses Mucopolysaccharidosis type VII Sialidosis Galactosialidosis | Dislocated lens | Methionine synthetase deficiency Sulfite oxidase deficiency |
| Macroglossia | Pompe disease Gangliosidoses Mucopolysaccharidoses Mucopolipidoses | Bone or limb deformities or contractures | Storage, peroxisomal, or connective tissue disorders Inborn errors of cholesterol biosynthesis |
| Dystonia or extrapyramidal signs | Gaucher disease type 2 Glutaric acidemia type 1 Krabbe disease Crigler–Najjar syndrome Bioppter defects | Thick skin | Mucopolipidoses Gangliosidoses Mucopolysaccharidoses |
| Macular “cherry-red spot” | GM1 gangliosidosis Galactosialidosis Niemann–Pick disease type A Tay–Sachs disease (GM2 gangliosidosis) | Desquamating, eczematous, or vesiculobullous skin lesions | Acrodermatitis enteropathica Organic acidemias Early-onset forms of porphyria |
| | | Ichthyosis | Gaucher disease type 2 Steroid sulfatase deficiency |
| | | Alopecia | Multiple carboxylase deficiency |
| | | Steely or kinky hair | Menkes disease |
| | | Persistent diarrhea | Glucose galactose malabsorption Congenital lactase deficiency Congenital chloride diarrhea Sucrase isomaltase deficiency Acrodermatitis enteropathica Congenital folate malabsorption Wolman disease Galactosemia |

For discussion of specific disorders, see Chapters 22 and 23.

Modern neonatology has one tool that was previously unavailable: the expanded newborn screen. This screening will diminish the probability of many disorders, and the newborn screening follow-up hotline should be on the speed dial of every neonatal intensive care unit. The only acutely presenting disorders not ascertained by these studies are most hyperammonemias and lactic acidoses. These test results are available immediately in any tertiary or secondary care hospital. With a high level of concern and near normal

levels of lactate and ammonia, the standard battery of metabolic studies should be performed only when the index of suspicion for a metabolic disorder is particularly high and no alternative explanation for the poor condition of the patient is likely. When deemed necessary, these studies should include plasma amino acid levels, plasma acylcarnitine levels, and urinary organic acid levels. The abnormalities associated with individual disorders are discussed in Chapter 22.

**TABLE
21.2****Characteristic or Unique Laboratory or Diagnostic Testing Outcomes in Inborn Errors (Major Examples)**

| Outcome | Error | Outcome | Error |
|--|---|---------------------------------------|--|
| Metabolic acidosis with or without increased anion gap | Organic acidemias Maple syrup urine disease Fatty acid oxidation defects β -Ketothiolase deficiency Ketogenesis defects Disorders of pyruvate metabolism Mitochondrial respiratory chain or electron transport chain defects, including Leigh disease Galactosemia Glycogen storage disease type 1 Gluconeogenesis defects | Thrombocytopenia | Organic acidemias Pearson syndrome |
| Respiratory alkalosis | Urea cycle disorders | Anemia | Organic acid disorders Wolman disease Pearson syndrome Severe liver failure Galactosemia |
| Hyperammonemia | Urea cycle disorders Methylmalonic acidemia Organic acidemias Fatty acid oxidation disorders | Vacuolated lymphocytes or neutrophils | Lysosomal storage disorders |

| | | Agenesis of corpus callosum | Pyruvate dehydrogenase complex deficiency Pyruvate carboxylase deficiency Mitochondrial respiratory or electron transport chain defects |

MRI, Magnetic resonance imaging.

Emergency Treatment

An acutely ill child with an inborn error of metabolism is an emergency, and rapid rescue treatment is mandatory. When one is considering a differential diagnosis, special emphasis should be placed on disorders for which there is treatment, as opposed to those for which there is no treatment. As with all acutely ill patients, supportive care, including cardiorespiratory, hemodynamic status, fluids, and electrolytes, are the mainstays of treatment. Transfer from institution to institution should not be performed unless the patient's condition is stable and there is adequate vascular access for emergency treatment. Transfer to a tertiary care center with experience in caring for these children is desirable and should be performed as quickly as possible.

Virtually all disorders require a maximum source of calories (150 cal/kg is desirable, but 120 cal/kg is a minimum target) to prevent or diminish catabolism, and glucose is the most important part of this, especially in the absence of primary lactic acidemia or acidosis. As much lipid as is safe should be added to compensate for the caloric deficit.

Hemodialysis will remove most metabolites rapidly, but this is an extreme intervention in a newborn. It should be performed routinely in extreme and symptomatic hyperammonemia (ammonia levels of 400 mol/L or more), and many would consider dialysis in severe acidosis caused by acids other than lactate or ketones. Once a diagnosis has been established, specific therapy can be

initiated. It is important to emphasize that during this period of generic therapy, prolonged deprivation of exogenous protein or amino acids will cause endogenous protein breakdown and exacerbate the metabolic process. As a result, protein is added to the intravenous support fluids after 36–48 hours, beginning with 0.25–0.5 g/kg per day and increasing gradually to maintenance levels of 1.2–1.5 g/kg per day, pending a definitive diagnosis and assuming that it is tolerated.

Inborn Errors of Carbohydrate, Ammonia, Amino Acid, and Organic Acid Metabolism

J. LAWRENCE MERRITT, II, AND RENATA C. GALLAGHER

KEY POINTS

- The establishment of universal newborn screening (NBS) for disorders of fatty acid, organic acid, and amino acid metabolism in the United States is a major public health accomplishment of the first decade of the 21st century.
- Early identification and treatment of affected newborns have decreased the morbidity and mortality associated with many of these conditions.
- Multiple disorders of intermediary and energy metabolism are *not* detected through NBS.
- The appropriate testing, including urine organic acid analysis, plasma acylcarnitine profile, and plasma amino acid analysis, should be performed in any symptomatic patient, even if the newborn screen result was “normal.”

Acute, life-threatening disease during the newborn period is a feature of many inborn errors of metabolism, including those of ammonia, carbohydrate, amino acid, fatty acid, ketone, and mitochondrial energy metabolism. Therefore it is critical that neonatologists are familiar with the clinical symptoms, laboratory findings, methods of diagnosis, and empiric—as well as specific—management of each of these classes of disease (Table 22.1). Importantly, while newborn screening (NBS) for some (but not all) disorders within each class has resulted in presymptomatic identification, allowing early institution of therapy and improved outcome for many affected individuals, clinical presentation before the development of symptoms may still occur because of environmental and biologic factors, as well as local NBS and follow-up protocols. Factors that prevent or delay identification by NBS include when the disease is not detected by NBS or is incompletely ascertained, when the newborn develops symptoms before the NBS result being reported, and when follow-up testing has not been completed (see Key Points). Thus familiarity with these diseases and their characteristic signs and symptoms is critical for early clinical recognition and the initiation of potentially life-saving empiric management (Table 22.2). Inborn errors of metabolism should also be considered in infants who develop symptoms outside of the immediate newborn period, as each of these disorders can have a later-onset presentation.

Carbohydrate Metabolism Disorders

Galactosemia

Elevated blood galactose, or *galactosemia*, is a result of a defect in one of three enzymes of the galactose metabolic pathway that converts galactose to glucose (Fig. 22.1). The disorder most clinically relevant in the newborn period is severe *galactose-1-phosphate uridylyltransferase* (GALT) deficiency. It is a cause of neonatal jaundice and coagulopathy and is life threatening. It is commonly referred to as “classic galactosemia.” This condition is the primary target of NBS for galactosemia. The other two enzyme defects that cause elevated blood galactose are *galactokinase* and *uridine diphosphate galactose-4-epimerase* deficiencies. Clinical features associated with each disorder are described later. In classic galactosemia, on the ingestion of lactose, a disaccharide of glucose and galactose, the substrate of the enzyme galactose-1-phosphate accumulates, as does galactose and the secondary metabolites galactitol and/or galactonate. Elevations of galactitol may cause characteristic “oil drop” cataracts that may be present at birth. The roles of the other metabolites in pathogenesis of the liver, kidney, brain, and ovarian dysfunction of severe GALT deficiency are not understood. They likely include the deficiency of galactose-1-phosphate conjugated to uridine, as well as toxicity of accumulating metabolites.

The frequency of classic galactosemia is estimated to be 1 in 60,000 to 1 in 75,000 births in the United States and Europe (Varela-Lema et al., 2016). There are also milder forms of unclear clinical significance, such as Duarte variant galactosemia, with enzyme activity of roughly 25% of wild type, which are frequently identified by abnormal NBS but are currently believed not to require treatment (Welling et al., 2017).

NBS methods for identification of classic galactosemia vary by state and include measurement of “total galactose” (galactose plus galactose-1-phosphate) and GALT enzyme activity (Pyhtila et al., 2015). Testing after an abnormal NBS may include DNA analysis to identify common mutations in the *GALT* gene. In states that measure analytes, children with galactokinase or epimerase deficiencies may be identified. These disorders will not be detected through screening for deficient GALT enzyme activity alone. The accuracy of NBS is dependent on information provided by the ordering

**TABLE
22.1****Presentations of Inborn Errors of Metabolism**

| | Newborn/ Early Onset | Acute Presentation | Chronic Presentation | Currently on Newborn Screening Panels |

nursery, as transfused red blood cells may cause a false-negative NBS for galactosemia. (Transfusion of red blood cells will also impact detection of hemoglobinopathies.) Infants transfused before NBS require follow-up testing for galactosemia and hemoglobinopathies at least 4 weeks after transfusion. Also, infants who have not received a lactose-containing feeding (i.e., breast milk or nonsoy-based formulas) before screening may not have elevated galactose levels and may have false-negative NBS if the screening method is analyte based. False-positive NBS results can occur in hot weather if the screening method is enzyme activity, as the enzyme is denatured in heat. Mutation analysis and enzyme activity help identify neonates with classic galactosemia, who have a poorer prognosis than those with variant (nonclassic) galactosemia.

At presentation, total blood galactose levels may be elevated with elevated red blood cell galactose-1-phosphate (Gal-1-P) and urine galactitol levels. During this phase of severe hypergalactosemia, positive reducing substances will be present in urine, but these resolve within hours with dietary restriction of galactose. There may be factitious elevation of glucose in affected individuals, as measured by bedside glucometers (Ozbek et al., 2015). Following the initiation of treatment with a lactose-free diet, Gal-1-P levels decrease but rarely normalize, remaining elevated for the lifetime

of the patient. There is a target range for treatment, and maintenance of Gal-1-P levels in treatment range through dietary restriction of galactose is the current goal of short- and long-term dietary therapy (Welling et al., 2016).

Untreated classic galactosemia may present with severe multi-organ (liver and kidney) disease in the first days to weeks of life. The most common clinical symptoms are vomiting, poor feeding, failure to thrive, and lethargy, with jaundice and hepatomegaly on physical examination. About 10% of affected neonates develop sepsis, often due to *Escherichia coli*; other causative organisms include *Klebsiella* and *Enterobacter* (Berry, 1993). Characteristic laboratory findings are indirect hyperbilirubinemia and apparent liver failure with markedly elevated coagulation parameters out of proportion to the transaminase elevations. With continued lactose/galactose ingestion, liver disease can progress to cirrhosis with portal hypertension and splenomegaly. Renal Fanconi syndrome may also develop. Cataracts may develop in the first few weeks of life in untreated individuals, while some neonates are born with cataracts.

Management of the liver disease involves dietary restriction of galactose and supportive care. The coagulopathy resolves over several days. A lactose-free formula should be initiated as soon as classic

galactosemia is suspected as this can be life-saving. An early change to soy formula may mask the symptoms of the disease. With early dietary restriction, improvement has been seen in severe clinical presentations and in neonatal mortality (Varela-Lema et al., 2016). While growth and feeding return to normal, treated individuals may develop long-term complications including speech and language disorders, cognitive and learning problems, cataracts, primary ovarian insufficiency (in most females), tremor, dystonia, coordination problems, or severe ataxia (Varela-Lema et al., 2016). The cause of these complications is unknown, and they may not be improved by dietary restriction (Waisbren et al., 2012).

Patients with classic galactosemia are advised to continue a lactose-restricted diet for their entire lives, but this diet does have significant risk of calcium and vitamin D deficiencies, and these must be supplemented. Dairy and high galactose nondairy foods including fruits, legumes, and vegetables are restricted. Not all galactose is exogenous; there is some endogenous galactose production. Treatment compliance is monitored through frequent assessment of Gal-1-P levels. The restriction of galactose-containing fruits and vegetables may not be necessary lifelong (Van Calcar et al., 2014). The impact of treatment for Duarte variant versus no treatment is unclear, and clinical practice remains highly variable across the United States.

NBS has changed the clinical outcome of classic galactosemia and when results are provided as early as 3 to 4 days of life—before significant clinical symptoms—hospitalization is often avoided. A recent systematic review of NBS for galactosemia in Europe identified significant variability in galactosemia screening methods, cutoff values, and screening ages. Mortality ranged from 0%–100% with no agreement regarding treatment of variant forms, or timing of clinical follow-up, and evidence in favor of NBS was considered insufficient. The greatest confounder of the cost–benefit assessment of NBS was the false-positive testing rate and the effects of these test results on families (Varela-Lema et al., 2016).

Epimerase Deficiency Galactosemia

Uridine diphosphate-galactose 4'-epimerase (GALE) deficiency has several forms. Generalized GALE deficiency may present similarly to GALT deficiency when the enzyme is deficient in all tissues. Peripheral or intermediate forms of GALE deficiency are associated with deficient enzyme activity in red blood cells, with normal or only partially decreased enzyme activity in other tissues (i.e., white blood cells or fibroblasts). For the peripheral or intermediate forms, children receiving a normal, lactose-containing diet will not become symptomatic. GALE deficiency may be detected on newborn screen in states that test for classic galactosemia by analyte. These children have elevated Gal-1-P levels with normal GALT enzyme testing. Individuals with generalized disease can develop severe liver and renal disease if untreated, and they can be diagnosed with GALE deficiency through assessment of activity in red blood cells. GALE deficiency is treated identically to GALT deficiency, when symptomatic (Fridovich-Keil et al., 1993).

Galactokinase Deficiency

Galactokinase (GALK) deficiency causes elevated galactose but not Gal-1-P. Affected individuals also have elevated galactitol and may develop dense cataracts if untreated. GALK deficiency is also associated with pseudotumor cerebri, but the disease does not cause systemic effects (Bosch et al., 2002). As for GALE deficiency, GALK deficiency may be detected on newborn screen in states that test for classic galactosemia by analyte. GALT enzyme testing is normal. Cataracts may develop in the neonatal period, and early

treatment may improve or resolve cataracts if infants are treated with galactose restriction before 4–8 weeks of life (Hennermann et al., 2011). Lifetime dietary galactose restriction may be necessary but is milder than that required for GALT deficiency.

Glycogen Storage Diseases

Glycogen storage diseases (GSDs) are due to abnormalities in glycogen synthesis or utilization for energy production. They are divided into types primarily affecting the liver (types I, IIIb, IV, VI, and IX), the muscles (types II, V, and VII), or mixed (type IIIa and forms of IX). Hypoglycemia is often a presenting symptom of the liver-based GSDs. Most GSDs are inherited in an autosomal recessive manner, except GSD IXa and IXd (hepatic and muscle phosphorylase kinase deficiencies, respectively), which are X-linked. Severe GSD II is associated with an infantile cardiomyopathy and is most likely to be encountered in the neonatal intensive care unit.

Hepatic Glycogen Storage Diseases

GSD I is due to glucose-6-phosphatase deficiency (von Gierke disease, Ia) or to deficient glucose-6-phosphate transport (Ib). Glucose-6-phosphatase plays a critical role in both glycogenolysis and gluconeogenesis (Fig. 22.1). The frequency of GSD type I is estimated to be 1 in 100,000 births, with 80% of cases being type Ia. The frequency is 1 in 20,000 in Ashkenazi Jews due to a founder mutation (Kishnani et al., 2014).

GSD I may not manifest in the neonatal period, as frequent newborn feeding may prevent symptomatic hypoglycemia and the development of hepatomegaly. Major clinical findings include failure to thrive, with an enlarged abdominal girth from hepatomegaly and hypoglycemia. Major laboratory findings are a rapid fasting hypoglycemia (typically within a few hours), with ketosis and lactic acidosis. Because of the high lactate level, individuals may be relatively asymptomatic from the hypoglycemia. Hypercholesterolemia, hypertriglyceridemia, and hyperuricemia may be seen in older individuals. Patients with GSD Ib additionally develop recurrent infections because of neutropenia and defective neutrophil function. Inflammatory bowel disease may develop in the first year of life. Diagnosis is now often confirmed through DNA sequencing of the *G6PC* (GSD Ia) and *SLC37A4* (GSD Ib) genes, although liver biopsy for enzyme activity may also be performed for diagnosis.

Therapy focuses on the prevention of hypoglycemia and resultant brain damage and growth failure, through frequent feedings and restriction of lactose and sucrose, as galactose and fructose derived from these feed into the blocked pathway (Kishnani et al., 2014). Continuous nasogastric feedings or boluses of uncooked cornstarch are essential at night and often during the day and result in improved glucose control and growth but do not completely correct other biochemical abnormalities. A comprehensive plan for treatment of intercurrent illnesses and emergencies is required. Neutropenia in type Ib may be treated with granulocyte colony-stimulating factor. Liver transplantation has been shown to improve metabolic control, fasting hypoglycemia, and growth (Boers et al., 2014). The disease also affects the kidneys including focal segmental glomerulosclerosis and progressive renal insufficiency.

Muscular Glycogen Storage Diseases

The most common and significant form of muscular GSD is type II, commonly called *Pompe disease* (*acid alpha-glucosidase deficiency* (abbreviated as GAA), also known as *acid maltase deficiency* or *lysosomal α -1,4-glucosidase deficiency*). This is the only GSD that is

• Fig. 22.2 Pompe Disease Electrocardiogram.

also a lysosomal storage disease (LSD), and it was the first identified LSD. Glycogen accumulates within the lysosome because of a defect in lysosomal-mediated degradation of glycogen. As for some other LSDs, enzyme replacement therapy has been developed for Pompe disease. This is the only current effective therapy for this disease.

Pompe disease has an estimated incidence of 1 in 40,000 in the Netherlands, based on the country's screening for three common mutations in newborn blood spots. The incidence ranges from 1 in 57,000 for late-onset disease to 1 in 138,000 for classic infantile disease (Ausems et al., 1999; Mechtler et al., 2012).

The classic infantile presentation of Pompe disease is hypotonia and hypertrophic cardiomyopathy. Creatine kinase, lactate dehydrogenase, and aspartate aminotransferase are elevated. The electrocardiogram is abnormal with a short PR interval and giant QRS complex in all leads, suggesting biventricular hypertrophy (Fig. 22.2). Late-onset presentations are of myopathy and have been diagnosed as early as the 2nd year of life. Diagnosis is made through the identification of decreased GAA activity in dried blood spots, fibroblasts, or muscle and confirmed via sequencing of the *GAA* gene (Zhang et al., 2006; Winchester et al., 2008). If the diagnosis is suspected, muscle biopsy can be avoided through blood spot and DNA testing but if performed will demonstrate vacuolar myopathy with glycogen storage within lysosomes and free glycogen

in the cytoplasm demonstrated by electron microscopy. The vacuoles are periodic acid-Schiff positive, digestible by diastase, and positive for acid phosphatase.

Decisions regarding which disorders are included on a state's NBS panel are made by each state, and some states now include Pompe disease. NBS in other countries has led to the initiation of early enzyme replacement therapy, which demonstrates improvements in cardiac size, muscle pathology, growth, and gross motor function in affected individuals but not in arrhythmias such as Wolff-Parkinson-White or in dysphagia or osteopenia (Chien et al., 2009; van Gelder et al., 2015). Long-term follow-up of early-treated individuals has demonstrated increased life span and increased ambulation with individuals not requiring mechanical ventilation (Chien et al., 2015). Gene therapy is being investigated with promising results in a mouse model of the disease (Falk et al., 2015; Todd et al., 2015).

Andersen disease, or GSD IV, is due to deficiency of glycogen branching enzyme, expressed in multiple tissues, and may manifest primarily as hepatic or muscular disease, with involvement of the heart and/or the nervous system. Two rare neuromuscular subtypes that present in the newborn period are the fatal perinatal neuromuscular subtype and the congenital neuromuscular subtype. The first presents with fetal akinesia sequence with polyhydramnios,

decreased fetal movement, fetal hydrops, and neonatal death or with hypotonia, muscular atrophy, arthrogryposis, and death in the neonatal period from cardiopulmonary failure (Magoulas and El-Hartab, 1993). The second presents with profound hypotonia, respiratory distress requiring mechanical ventilation, dilated cardiomyopathy, and death in early infancy (Escobar et al., 2012). The classic GSD IV subtype is the progressive hepatic subtype. Children are often normal at birth but develop failure to thrive, hypotonia, and potentially progressive liver dysfunction leading to cirrhosis and cardiomyopathy requiring liver and heart transplantation, respectively. Death may result from progressive cardiomyopathy despite liver transplantation. GSD IV is a rare autosomal recessive disorder, and diagnosis is confirmed through DNA sequencing of the *GBE1* gene or by detection of abnormal enzyme activity in muscle, liver, or skin fibroblasts.

Fructose Metabolism

The primary disorder of fructose metabolism is *hereditary fructose intolerance* (HFI). This is a rare autosomal recessive disorder triggered by ingestion of fructose, sucrose, or sorbitol, which may present clinically when infants are weaned from breast milk or formula and juice or fruit are added to the diet or when they receive a formula that contains fructose (Baker et al., 1993). Infants or neonates who are given sucrose solutions for pain relief during minor procedures may develop hypoglycemia, and a diagnosis of HFI should be considered in these cases. Clinical findings include pallor, lethargy, poor feeding, vomiting, loose stools, poor growth, hepatomegaly, and hypoglycemia, lactic acidemia, hyperuricemia, transaminase elevations, and positive urine reducing substances with ingestion of fructose. Renal tubular dysfunction may be present. Diagnostic testing consists of measuring enzyme activity in liver tissue and/or sequencing of *ALDOB*. Treatment includes elimination of fructose, sucrose, and sorbitol from the diet and medications. In practice, complete elimination of these can be quite difficult but is necessary for optimal outcome. Neonatal screening for HFI was investigated in 1996 in the United Kingdom, as early strict dietary treatment may avoid disease sequelae, but was not implemented (James et al., 1996).

Fructose-1,6-bisphosphatase deficiency is not a disorder of fructose metabolism. It is a disorder of gluconeogenesis, although as with other disorders of gluconeogenesis, therapy may include some limitation of dietary fructose. Patients may present in the newborn period with lactic acidosis and hypoglycemia when glycogen reserves are limited and then be clinically silent and present later (typically before 2 years of age) during times of fasting or following a fructose load. Acute crisis presents similarly to HFI and GSD Ia, as these are within the differential. This is a very rare disorder, with an estimated incidence between 1 in 350,000 and 1 in 900,000 and is autosomal recessive resulting from mutations in the *FBP1* gene (Lebigo et al., 2015).

Urea Cycle Disorders

Removal of excess nitrogen is the function of the urea cycle. Urea cycle disorders (UCD) result from inhibition of the synthesis of urea from ammonia and classically manifest in the newborn period, although these may manifest at any age. Symptoms of hyperammonemia are provoked during episodes of protein catabolism (e.g., because of illness and poor oral intake) or dietary protein excess and are treated by controlling protein catabolism through dietary limitation of protein and removing offending toxic products (chiefly ammonia) with ammonia-scavenging medications or dialysis. UCDs

are frequently classified as proximal (mitochondrial) and distal (cytoplasmic). The three proximal UCDs are *N-acetylglutamate synthase deficiency* (NAGS), *carbamyl phosphate synthetase I* (CPSI) *deficiency*, and *ornithine transcarbamylase deficiency* (OTCD). The distal UCDs are *argininosuccinate synthetase deficiency* (known as *ASS deficiency* or *citrullinemia type I*, *CITI*), *argininosuccinate lyase deficiency* (also known as *argininosuccinic aciduria*, *ASA*), and *arginase 1 deficiency*. Additionally, disorders of the urea cycle include two of mitochondrial membrane transport. Deficiency of the mitochondrial ornithine transporter 1 is a cause of hyperammonemia, hyperornithinemia, and homocitrullinuria syndrome, and deficiency of the mitochondrial aspartate–glutamate transporter is a cause of citrullinemia type II or citrin deficiency. A defect of a plasma membrane transporter affects the renal tubular transport of cationic amino acids, including lysine, arginine, and the amino acids required for urea cycle function, and results in *lysine protein intolerance*, a multisystem disorder that only rarely manifests with neonatal hyperammonemia. Incidence estimates of all UCDs are 1 in 35,000 births, with OTCD, the most common UCD, estimated at 1 in 56,500 births (Summar et al., 2013). All UCDs are autosomal recessive except for OTCD, which is X-linked. Roughly 20% of heterozygote females manifest symptoms at some time in their life, and some of these present in the newborn period.

One complete turn of the urea cycle will produce a molecule of urea from two molecules of ammonia and one of bicarbonate. The nitrogen in ammonia is generated from the hepatic nitrogen pool of amino acids including glutamine, glutamate, and glycine. *N-acetylglutamate* is the product of the first enzyme in the cycle and is an essential activator of carbamyl phosphate synthetase I, which converts ammonia and bicarbonate into carbamyl phosphate. Ornithine and carbamyl phosphate are condensed by ornithine transcarbamylase to generate citrulline. Citrulline is combined with aspartate by argininosuccinate synthetase to create argininosuccinic acid. Fumarate is released from this by argininosuccinate lyase to create arginine. Urea is generated from arginine by arginase 1 and is excreted while ornithine reenters the urea cycle (Fig. 22.3).

Clinical symptoms in the newborn period are similar for all UCDs and are due to hyperammonemia. Severely affected newborns exhibit a progressive altered level of consciousness with drowsiness and lethargy progressing to unresponsiveness, beginning after 24 hours of life. Typical symptoms include poor feeding, vomiting, hyperventilation (caused by ammonia elevation and resulting in a primary respiratory alkalosis), and temperature instability. There may be peripheral circulatory failure that progresses to multiorgan failure. Marked hyperammonemia causes acute encephalopathy, leading to seizures, coma, and death if untreated. Ammonia levels should be checked in any infant with these symptoms, which may mimic sepsis or intestinal obstruction, and, if elevated, should be treated rapidly. Later-onset presentations include recurrent emesis, ataxia, liver dysfunction or apparent failure with coagulopathy, postpartum psychosis, and other psychiatric symptoms such as aggression, agitation, mania, and personality changes (Serrano et al., 2010).

Without rapid treatment severe UCDs are almost always fatal or result in severe and irreversible brain damage. The primary goal of treatment is to remove excess ammonia, which is neurotoxic. Its effects include alterations in amino acid pathways, neurotransmitters, energy production, nitric oxide synthesis, axonal and dendritic growth, and signal transduction in the developing brain. Additionally, excess glutamine may cause cerebral swelling and edema in the mature brain (Braissant et al., 2013). Acute hyperammonemic episodes may be associated with transaminase elevation and synthetic liver dysfunction, and it is important to assess these.

• **Fig. 22.3** Overview of urea cycle metabolism (blue) and nitrogen scavenger therapies (green). Stars indicate supplementation with citrulline or arginine. Plus sign indicates allosteric activator of carbamyl phosphate synthetase I. Dashed line indicates accumulation of orotic acid in ornithine transcarbamylase deficiency. Purple indicates transport between the mitochondrion and the cytosol. ARG, arginase; ASL, argininosuccinate lyase; ASS, argininosuccinate synthetase; ATP, adenosine triphosphate; CPSI, carbamyl phosphate synthetase I; CO_2 , carbon dioxide; NAGS, N-acetylglutamate synthase; NH_3 , ammonia; OTCD, ornithine transcarbamylase.

Individuals affected by proximal UCDs have been reported to present earlier in life, to have a higher peak ammonia level, and to have a longer average length of stay compared with patients with distal UCDs. Reports identify the age at first admission for hyperammonemia as less than or equal to 2 days in 55% of OTCD and CPSI patients and at less than 7 days in 84% of these patients (Ah Mew et al., 2013). For OTCD patients, nearly half of the males but only 4% of females will present between 0 to 30 days of age (Summar et al., 2008).

The critical laboratory abnormality in a UCD is elevated plasma ammonia. While artifactual elevations may occur due to problems with sample collection and processing, hyperammonemia in a newborn is a medical emergency, and, if elevated, the test should be repeated and additional evaluation and management initiated immediately. Normal plasma ammonia levels in newborns are as high as 110 $\mu\text{mol/L}$ (although care should be taken to confirm units as some laboratories report mg/dL). A level of greater than 150 $\mu\text{mol/L}$ (255 mg/dL) should prompt suspicion of, and evaluation for, an inborn error of metabolism in neonates. In older infants, children, and adults the reference range for ammonia is less than 35 $\mu\text{mol/L}$ (60 mg/dL). In primary or secondary disorders of the urea cycle that present in the newborn period, ammonia levels may be in the thousands. The differential diagnosis of hyperammonemia in the newborn period includes urea cycle defects, organic acidemias, fatty acid oxidation disorders (FAODs), and transient hyperammonemia of the newborn (THAN). In UCDs the hyperammonemia is often associated with a respiratory alkalosis caused by the effect of ammonia on the respiratory control centers in the brainstem. A primary respiratory alkalosis in a

newborn should prompt a physician to order an ammonia level. Early involvement of a geneticist with experience in the evaluation and management of inborn errors of metabolism is critical. Specialized biochemical laboratory testing should include plasma amino acids, total and free plasma carnitine, plasma acylcarnitine profile, total plasma homocysteine, plasma B12 level, urine organic acids, urine amino acids, and a quantitative urine orotic acid.

In proximal UCDs, there is decreased citrulline on plasma amino acid analysis, while patients with distal UCDs have either elevated citrulline (in CIT1 and ASA deficiency), elevated argininosuccinic acid (in ASA deficiency), or elevated arginine (in arginase deficiency). In OTCD, increased urinary orotic acid is present and may be identified on urine organic acid analysis, but a quantitative value is recommended because of variability in detection. NBS for CIT1, ASA, and arginase deficiency is performed through measurements of citrulline (CIT1, ASA) and arginine (arginase deficiency) in blood spots as these are elevated in these conditions. Proximal UCDs are not well identified on NBS because of the poor sensitivity of low citrulline levels, and most states do not have a low citrulline cutoff. When suspected clinically or through NBS, further evaluation should include metabolite testing of blood and urine, as previously described, and confirmation of a diagnosis is generally performed through DNA testing. For OTCD this should include analysis for gene deletions, as sequencing alone detects just over 80% of patients (Yamaguchi et al., 2006; Shchelochkov et al., 2009). In some cases, liver biopsy and enzyme analysis of liver tissue are required.

Hemodialysis is the primary method for rapid removal of ammonia. No clear guidelines have been established for initiation

of hemodialysis, but common indications include a rapidly increasing ammonia level, the presence of neurologic symptoms, or an ammonia level of greater than 400 $\mu\text{mol/L}$. Neurologic outcomes were improved when peak ammonia concentration was less than 180 $\mu\text{mol/L}$ and poorer when greater than 360 $\mu\text{mol/L}$ (Kido et al., 2012). Continuous arteriovenous hemofiltration (CAVH) provides a lower clearance rate but has the added benefit of continuous use and a lesser likelihood of major swings in intravascular volume that can exacerbate an already fragile state and cerebral edema. Ammonia clearance with peritoneal dialysis is approximately one-tenth that of CAVH and is not recommended for UCD therapy in the newborn period. Ammonia is not cleared effectively by exchange transfusion.

Alternative pathway or nitrogen-scavenging therapies are effective in helping to control ammonia levels and are critical in acute and chronic management (Fig. 22.3). When hyperammonemia is recognized and a UCD suspected, alternative pathway therapy can be rapidly implemented before hemodialysis, continued throughout, and maintained afterward and transitioned from intravenous (IV) to oral therapy for chronic management. The only approved IV therapy for treatment of hyperammonemia is sodium benzoate plus sodium phenylacetate (Ammonul). Arginine becomes an essential amino acid in severe early urea cycle defects; it stimulates the CPSI enzyme and is required for urea cycle function as it is one of the amino acids that comprises the urea cycle. It should be provided IV for suspected neonatal OTCD or CPSI and is especially effective in patients with CIT1 and ASA. It should not be given in known or suspected arginase 1 deficiency. Ammonul is rarely stocked except in pharmacies of tertiary care metabolic centers, and 10% arginine HCl is commonly available.

Nitrogen-scavenging therapies can effectively help control mild-to-moderate hyperammonemia in combination with other therapies and are critical to the acute management of marked hyperammonemia. A prospective study of IV sodium benzoate and sodium phenylacetate in neonatal hyperammonemia demonstrated the ability of these medications to lower plasma ammonia levels and improve survival (Enns et al., 2007). In acute management of hyperammonemia Ammonul is given as a loading dose of 250 mg/kg (of sodium benzoate) over 90 minutes followed by a 250 mg/kg dose over 24 hours by continuous IV (Summar, 2001). Arginine hydrochloride should be provided in known or suspected cases of NAGS, CPSI, or OTCD and is given as a 250 mg/kg loading dose over 90 minutes followed by a 250 mg/kg 24-hour maintenance dose. The dose is 600 mg/kg for known or suspected CIT1 or ASA (Summar, 2001). Also critical is reversal of catabolism, and age appropriate and higher calories must be provided by IV glucose at high concentration and IV intralipid (once a disorder of fat metabolism has been excluded). Parenteral nutrition, including provision of catabolism-sparing essential amino acids, should be initiated when ammonia has been controlled, ideally within 24 to 36 hours of the initiation of treatment. This treatment should be performed in collaboration with a clinical biochemical geneticist with experience in the treatment of UCDs.

Chronic management of infants with UCDs consists of providing adequate dietary protein, which will require a combination of natural (whole) protein from a regular infant formula as well as a special metabolic formula consisting of only essential amino acids to decrease the nitrogen burden; oral/enteral ammonia-scavenging medications; and arginine or citrulline, depending on the defect and severity. Also critical is the prevention of protein catabolism during times of illness or other physiologic stress, and an emergency sick-day diet and emergency letter should be provided at hospital

discharge. Children must be monitored frequently and medications and diet adjusted to prevent hyperammonemia and to allow adequate growth without overrestriction of protein resulting in poor growth and provoking catabolism. Long-term management requires a multidisciplinary team of a clinical biochemical geneticist, biochemical nutritionist, and genetic counselors and, in some cases nurses, a neurodevelopmental pediatrician, a neurologist, and rehabilitative medicine specialist, depending on the presence and severity of early brain injury.

Historically, the outcome of individuals with severe neonatal-onset CPSI or OTCD has been poor. A 2005 review estimated a poor outcome with a mortality of 84% in neonatal-onset cases and 28% in late-onset cases, before the use of nitrogen-scavenging therapies in Europe (Nassogne et al., 2005). When reviewing survival according to age, diagnosis, and first or recurrent episodes, the lowest survival is seen in male OTCD neonates at first episode. In an open label trial, newborns less than 30 days old had survival rates of 73% compared with 94% in infants greater than 30 days of age (Enns et al., 2007). In a 2009 study, in neonatal-onset cases intellectual disability was reported at almost 50%, compared with historical estimates of 60%–80% (Krivitzky et al., 2009). Currently, early liver transplantation in the first year of life, especially if initial rescue therapy has limited the peak and duration of hyperammonemia, is recommended (Campeau et al., 2010). Early recognition of hyperammonemia and rapid lowering of ammonia is critical to decreasing the extent and severity of early brain injury (Bireley et al., 2012).

Transient Hyperammonemia of the Newborn

THAN is most common in preterm newborns less than 36 weeks' gestational age that have a birth weight of less than 2.5 kg. Typically, it occurs following respiratory distress syndrome in the first 24 hours of life, and coma develops within the first 48 hours of life (Ballard et al., 1978). Serum ammonia levels can surpass 1500 $\mu\text{mol/L}$, and infants may require hemodialysis and protein restriction (Stojanovic et al., 2010).

The cause of this disease is unknown, although in some cases it may be due to a patent ductus venosus. Doppler ultrasound of the portal vein should be performed to evaluate for a clot in the portal vein. Plasma amino acid levels may have elevations of citrulline and arginine. The glutamine-to-ammonia ratio may distinguish this from a urea cycle defect (glutamine to ammonia ratio <1.6 in THAN, ensuring units are the same). There may be no respiratory alkalosis (Stojanovic et al., 2010). The mortality rate in THAN appears to be linked to the duration of coma; outcome can be good in surviving infants, and long-term treatment and protein restriction may not be necessary.

Amino Acid Metabolism Disorders

Maple Syrup Urine Disease

Maple syrup urine disease (MSUD) is a rare autosomal recessive inborn error of amino acid metabolism caused by branched-chain α -ketoacid dehydrogenase (BCKAD) complex deficiency. This enzyme is involved in the metabolism of the three branched-chain amino acids (BCAAs), leucine, isoleucine, and valine, at the step of conversion of each of their respective α -ketoacid derivatives into their decarboxylated coenzyme A (CoA) metabolites in the mitochondria (Fig. 22.4). The enzyme complex is composed of three components, E1, E2, and E3. E1 has two subunits, E1 α

long-term mental health (Muelly et al., 2013). Liver transplantation appears to result in similar outcomes when compared with those who have not had transplantation, but liver transplant may prevent further neurocognitive impairment from prevention of injury during recurrent acute events (Mazariegos et al., 2012).

Long-term MSUD treatment focuses on a BCAA-free formula balanced with the provision of sufficient BCAAs to maintain normal growth and development. The goal is that plasma leucine, isoleucine, and valine levels are in the normal range, though this may be difficult to achieve outside of infancy. Affected individuals must be closely monitored, and careful management by a biochemical genetic nutritionist is critical. Care must be given to ensure adequate supplementation with isoleucine and valine as BCAA-free formulas may lead to overrestriction of these. Overrestriction of isoleucine can result in anemia and a severe exfoliative rash similar to acrodermatitis enteropathica. A rare thiamine-responsive variant of MSUD may show improved BCAA levels and a decreased need for protein restriction with thiamine supplementation.

Tyrosinemia Type 1

Tyrosinemia type 1 (TYR1), or *hepatorenal tyrosinemia*, is an autosomal recessive disorder caused by a deficiency of the enzyme fumarylacetoacetate hydrolase as a result of mutations in the *FAH* gene. This enzymatic reaction is the last in the catabolism of phenylalanine and tyrosine to fumaric acid and acetoacetate, and the accumulation of tyrosine is due to other accumulating metabolites. The primary metabolites that accumulate are maleylacetoacetic acid and fumarylacetoacetic acid, and these both result in the elevation of succinylacetone. This compound is pathognomonic for this disease and is the primary confirmatory metabolite identified on urine organic acid analysis. It is a more sensitive and specific marker than tyrosine in NBS but is not available in all NBS programs. The estimated incidence is 1 in 100,000 to 1 in 120,000 in the general population. The incidence is higher in specific populations with estimates of 1 in 60,000 to 1 in 74,000 in Norway and Finland, 1 in 16,000 in Quebec, and 1 in 1846 in the Saguenay-Lac Saint-Jean region of Quebec because of common founder mutations in these areas (Sniderman King et al., 1993).

The phenotype is variable. One presentation is of an acute, early-onset, severe liver disease at less than 2 months of age; there is also an infantile-onset presentation and a chronic presentation after 1 year of age. The acute early-infantile presentation may be fatal with hepatomegaly, jaundice, elevated transaminases, and profound prolongations of prothrombin time and partial thromboplastin time. Affected individuals develop a renal Fanconi syndrome with generalized aminoaciduria, glycosuria, hypophosphatemia, hypouricemia, proteinuria, and an unusual urine odor of “boiled cabbage.” Children with the chronic phenotype exhibit liver disease, hypophosphatemic rickets as a result of the renal Fanconi syndrome, cardiomyopathy (in 20%–30%), and porphyria-like neurologic crises with abdominal pain, peripheral neuropathy, and respiratory failure (Sniderman King et al., 1993).

Plasma amino acid analysis will demonstrate elevated tyrosine levels, but this is not diagnostic as elevations of tyrosine are nonspecific and may be found, along with hypermethioninemia, in any disease causing liver dysfunction. Serum alpha fetoprotein levels are abnormally high. The identification of succinylacetone on urine organic acid analysis is diagnostic, and this may be detected within the first 12 hours of life (Schlump et al., 2010). As for most metabolic disorders, the characteristic metabolite abnormalities may not be present or detectable at all times.

NBS has allowed early treatment with 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC), and this has improved clinical outcome (Mayorandan et al., 2014; McKiernan et al., 2015). Treatment for TYR1 includes NTBC, which inhibits *p*-hydroxyphenylpyruvate dioxygenase, a proximal enzyme in the pathway, reducing the accumulation of succinylacetone but resulting in increased tyrosine levels. NTBC improves liver and renal disease but requires the implementation of a low-tyrosine, low-phenylalanine diet for improved neurologic outcome (Bendadi et al., 2014). Early treatment, ideally within the first month of life, results in a significant reduction in the development of acute liver disease, hepatomegaly, cirrhosis, hepatocellular carcinoma, renal dysfunction, rickets, and the need for liver transplantation (Mayorandan et al., 2014). Before the use of NTBC, most infants with the early-onset form of TYR1 died in early to late infancy. Unfortunately, patients treated with NTBC have shown impaired cognitive outcomes including a lower intelligence quotient, sub-optimal executive functioning (working memory and cognitive flexibility), and social cognition (face recognition and the identification of facial emotion) when treated with a natural protein-restricted diet (Bendadi et al., 2014; van Ginkel et al., 2016). Dietary overrestriction leading to hypophenylalaninemia may be the cause of these neurocognitive deficits, poor growth, cortical myoclonus, and eczema, although these have been seen to improve or resolve following phenylalanine supplementation (van Vliet et al., 2015).

One of the most severe complications of TYR1 is the development of hepatocellular carcinoma, typically occurring in later presentations in older children. Monitoring through serial liver ultrasounds and alpha fetoprotein levels is necessary. Treatment with NTBC will improve the biochemical markers and liver dysfunction, but liver transplantation may still be necessary in those who are NTBC-resistant or who have chronic liver disease or poor quality of life (Mayorandan et al., 2014).

Other forms of tyrosinemia may be detected with elevated tyrosine levels on NBS or plasma amino acid analysis. Tyrosinemia type 2, or oculocutaneous tyrosinemia, presents with corneal tyrosine crystals causing photophobia and hyperkeratotic plaques on the hands and soles of the feet. Tyrosinemia type 3 is extremely rare and has a variable phenotype including ataxia and mild mental retardation (Scott, 2006).

Transient tyrosinemia of the newborn is common in premature infants and is probably the most common disturbance of amino acid metabolism identified on NBS. It is due to delayed maturation of *p*-hydroxyphenylpyruvate dioxygenase or liver immaturity.

Nonketotic Hyperglycinemia

Glycine encephalopathy, also termed *nonketotic hyperglycinemia* (NKH), is an autosomal recessive disorder of the catabolism of glycine to carbon dioxide and ammonia (Van Hove et al., 1993). The incidence is about 1 in 60,000. The glycine cleavage system is composed of four proteins, glycine decarboxylase (GLDC), amino-methyltransferase (AMT), the glycine cleavage H protein, and lipoamide dehydrogenase. These are also called the *P* (pyridoxal-phosphate), *T* (tetrahydrofolate), *H* (hydrogen), and *L* (lipoamide) proteins, respectively, for the cofactor each utilizes. GLDC removes carbon dioxide, the AMT protein removes ammonia, the H protein removes the hydrogen, and the L protein regenerates the reduced form of the protein (Van Hove et al., 1993). The majority of affected individuals have mutations in the *GLDC* or *AMT* genes (Swanson et al., 2015). The pathophysiology is likely related to glycine's role in the CNS as both an inhibitory and an excitatory

neurotransmitter. The most common form of the disorder manifests in the 1st week of life as apnea and treatment refractory seizures associated with a burst-suppression pattern on electroencephalogram (EEG). This neonatal-onset form is associated with a very poor prognosis, even with early diagnosis and treatment (Swanson et al., 2015; Bjoraker et al., 2016). There are milder forms of the disorder that manifest in the first months of life or later.

The diagnosis of NKH is based on both the absolute value of glycine in cerebrospinal fluid (CSF) and on the ratio of CSF glycine to plasma glycine. CSF and plasma amino acids must be obtained concurrently. However, the presence of blood in the CSF invalidates the results as CSF amino acid values will not be accurate (Applegarth and Toone, 2001). CSF glycine is generally greater than 40 $\mu\text{mol/L}$ in affected individuals, and a CSF-to-plasma glycine ratio of 0.08 or greater is considered diagnostic of NKH (Swanson et al., 2015). This disorder is not identified through NBS because of high false-positive rates of blood spot glycine levels.

One goal of treatment is to lower CSF glycine through high-dose sodium benzoate therapy. Benzoate is conjugated with glycine to form hippuric acid, which is excreted. In addition, dextromethorphan, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, is prescribed to counteract the activation of the NMDA receptor by glycine. Restriction of dietary protein to restrict the amino acid glycine is not an effective therapy. Other care is supportive as the majority of affected individuals have profound intellectual disability and develop spastic quadriplegic cerebral palsy. Mildly affected individuals with a later-onset presentation with autism have been described. Withdrawal of support in the newborn period has been performed because of the poor prognosis, but the existence of a “mimic” of the disorder associated with identical, but transient, biochemical and clinical features—and with a good outcome—may complicate this decision (Boneh et al., 2008).

Recently, two new classes of disorders that have a secondary effect on the glycine cleavage system have been described. One class was identified through candidate gene sequencing of individuals with defects in the glycine cleavage system that lacked mutations in the known causative genes (Baker et al., 2014). The two classes are defects in lipoate synthesis, as lipoate is a cofactor of the L protein, and defects in iron–sulfur cluster biogenesis, as lipoate synthase is an iron–sulfur-containing protein. Affected individuals with defects in genes in both pathways have been described. The disorders have unique clinical and biochemical features, and all have deficient glycine cleavage (Mayr et al., 2014). It is important to consider these variant disorders in a neonate with apparent NKH. DNA testing should be performed to confirm the correct diagnosis, as the results are necessary for accurate treatment, prognosis, and genetic counseling.

Hyperhomocystinemias and Remethylation Disorders

In humans, as the essential amino acid methionine is converted to homocysteine, a methyl group is provided for many different methylation reactions. Homocysteine may then either be metabolized to cysteine (the transsulfuration pathway) via cystathionine β -synthase or be remethylated back to methionine; defects in these enzymes may lead to homocystinemia (or homocystinuria).

Classic homocystinuria is caused by an autosomal recessive deficiency of the cystathionine β -synthase enzyme as a result of mutations in the *CBS* gene and rarely presents in early infancy. The population frequency is estimated to be between 1 in 1800 and 1 in 900,000. NBS detects elevated methionine levels, but this will not detect all affected infants, particularly those with the

pyridoxine-responsive form of the disease. Early treatment improves clinical outcomes, including ectopia lentis, myopia, mental impairment, a marfanoid body habitus, osteoporosis, thromboembolic events, and behavioral problems (Morris et al., 2017). Infants may present with thrombosis, and homocysteine should be assayed for any thrombotic event, regardless of the NBS result.

Defective methionine remethylation may be due to methionine synthetase deficiency, methionine synthetase reductase deficiency, 5-methylenetetrahydrofolate reductase (MTHFR) deficiency, and other defects in cobalamin metabolism or transport (a cofactor for methionine synthase). Newborns may come to clinical attention with encephalopathy with lethargy, feeding difficulties, hypotonia, seizures, pancytopenia with megaloblastic anemia, cardiomyopathy, and optic atrophy and retinopathy (Morris et al., 2017). Previously thought to be rare, these disorders are now identified more frequently as a result of NBS, and false positives for these may be due to maternal nutritional cobalamin deficiency. The disorders of cobalamin intracellular processing or transport are identified by decreased methionine, elevated homocysteine, and/or elevated methylmalonic acid and C3-(methylmalonyl)-acylcarnitine levels (see *Methylmalonic Acidemia*). Infants may quickly develop postnatal failure to thrive, and appropriate treatment, which may include hydroxocobalamin, betaine, folinic acid, carnitine, and methionine supplementation, is now resulting in improvements in clinical outcome (Morris et al., 2017).

Patients with MTHFR deficiency may present as neonates with decreased consciousness, hydrocephalus, hypotonia, and feeding difficulties. There may be severe cortical atrophy and brain lesions caused by thromboses of the arteries or veins. This may present as an acute disorder of intoxication in the newborn period. Treatment with high-dose betaine, which enhances the remethylation of homocysteine to methionine through an alternate betaine–homocysteine methyltransferase pathway, is reported to improve or normalize development (Morris et al., 2017).

Early detection of disorders of remethylation and of classic homocystinuria is possible through NBS, which utilizes a high methionine level to detect classic homocystinuria and a low methionine level to detect remethylation disorders. NBS is not fully sensitive or specific for these disorders. One cause of false positives is heterozygous mutations in the *MAT1A* gene causing hypermethioninemia, which may be benign. The sensitivity of NBS for cystathionine β -synthase deficiency is improved by using elevated methionine levels together with methionine:phenylalanine and methionine:total homocysteine ratios, although measurement of total homocysteine is not available universally (Huemer et al., 2015). NBS for some remethylation disorders is possible by detection of low methionine levels with elevated C3-acylcarnitine levels, depending on the individual state programs (Huemer et al., 2015). Confirmatory DNA testing is available for all of the disorders.

Phenylketonuria

Phenylketonuria (PKU) is an autosomal recessive disorder resulting from deficiency of phenylalanine hydroxylase (PAH). It is the most common inborn error of amino acid metabolism, affecting about 1 in 10,000 northern European or east Asians, 1 in 2600 individuals in Turkey, and 1 in 4500 in Ireland but only 1 in 143,000 in Japan and 1 in 200,000 both in Finland and among those of Ashkenazi Jewish ancestry (Regier and Greene, 1993). The enzyme defect results in decreased levels of tyrosine. PAH requires the cofactor tetrahydrobiopterin (BH_4), therefore PAH enzyme deficiency may also result from a deficiency in the synthesis or recycling of BH_4 . Disorders of BH_4 metabolism may result in elevated

phenylalanine levels and should be tested for when performing follow-up NBS testing, as treatment and outcomes differ (Camp et al., 2014). BH_4 is also a cofactor for tyrosine hydroxylase, tryptophan hydroxylase, and nitric oxide synthase, and so BH_4 deficiency will also lead to impaired levels of L-dopa, dopamine, norepinephrine, melanin, serotonin, citrulline, and nitric oxide. PKU does not present with symptoms in the newborn period. It is a cause of intellectual disability, and there are no systemic manifestations. Treatment, however, should be instituted in the first several weeks of life for optimal outcome, and it is important that physicians caring for newborns are familiar with the evaluation and management of newborns with an abnormal NBS for PKU.

PKU was the first disorder for which NBS was implemented in the 1960s. NBS for PKU is a model for preventative and personalized medicine, as well as for public health screening and intervention. The blood spot phenylalanine level and the phenylalanine:tyrosine ratio will be elevated and detected by NBS. The blood spot should be collected after 24 hours of age following breastfeeding or formula feeding. Elevated urine phenyl ketones and phenylacetic acid result in a “mousey” urine odor. Diagnosis should be confirmed through plasma amino acid analysis and testing for BH_4 metabolism disorders in blood and urine. DNA sequencing of the *PAH* gene may provide helpful information for genetic counseling and treatment.

Untreated PKU patients will develop developmental and intellectual disabilities, eczema, hypopigmented skin and hair, and epilepsy in infancy and at older ages. Dietary phenylalanine restriction with strict compliance is necessary to prevent intellectual disability and other features. Dietary compliance may be difficult for teenagers and adults, but lifelong dietary treatment is necessary to avoid neuropsychiatric symptoms such as inattention, hyperactivity, depression, and anxiety (Bilder et al., 2016). Mothers who are poorly compliant during pregnancy and have phenylalanine levels above the recommended treatment range may have children with microcephaly, fetal growth restriction, congenital heart defects, and other malformations, known as *maternal PKU syndrome*. Attaining plasma phenylalanine levels within treatment range before the 8th week of pregnancy is essential and ideally should be achieved before pregnancy. Phenylalanine levels should be maintained between 120 and 360 $\mu\text{mol/L}$, the typical treatment range in the United States, throughout the pregnancy (Camp et al., 2014).

Dietary therapy for PKU is effective and involves a low natural-protein diet supplemented with phenylalanine-free medical formula to ensure adequate total protein and micronutrients. An adequate amount of phenylalanine from whole protein in formulas and foods is necessary for normal growth and protein synthesis, with a goal of maintaining plasma phenylalanine levels less than 360 $\mu\text{mol/L}$ (Camp et al., 2014). Sapropterin (a synthetic form of the BH_4 cofactor) may be beneficial in lowering phenylalanine levels in the 25%–50% of patients who are sapropterin responsive. Newer therapies being developed include using large neutral amino acids that compete for the same gut and brain transporter as phenylalanine in older children and adults, to lower brain phenylalanine levels. There is a current clinical trial of polyethylene glycol-conjugated phenylalanine ammonia lyase that converts phenylalanine to transcinnamic acid and is given subcutaneously to reduce plasma phenylalanine levels in patients on normal diets (Camp et al., 2014).

Organic Acidemias

The classical organic acidemias (or acidurias, the terms are interchangeable) are characterized by systemic illness and presentation

in the newborn period in the severe forms and include methylmalonic acidemia (MMA), propionic acidemia, and isovaleric acidemia. These are due to defects in pathways that affect the catabolism of one or more of the BCAAs (leucine, isoleucine, and valine) as well as other amino acids (Fig. 22.4). An organic acid is any organic compound that contains a carboxy functional group but no α -amino group. They are intermediates in multiple pathways, including those of amino acid, fatty acid, cholesterol, and neurotransmitter metabolism. Disorders of fatty acid oxidation, ketone body metabolism, and lactic acid metabolism may also be detected through organic acid analysis.

Before NBS, these disorders were diagnosed only after patients became symptomatic, unless there was a known affected family member. While early presentation does occur before NBS results are available, with widespread NBS it is more common to be confronted with an asymptomatic or early symptomatic patient and a differential diagnosis that is based on the NBS results. Presenting symptoms of the classic organic acidemias in the neonate result from the progressive hyperammonemia, keto lactic acidosis, and hypoglycemia.

Methylmalonic Acidemia

Multiple genetic defects can lead to the elevation of methylmalonic acid. Isolated MMA is caused by methylmalonyl-CoA mutase enzyme deficiency as a result of mutations in the *MUT* gene. Adenosylcobalamin is a required cofactor for the mutase enzyme, and cobalamin (vitamin B_{12}) disorders of processing or transport may present with elevations of methylmalonic acid alone or in combination with elevated homocysteine, as homocysteine is also metabolized by a cobalamin-dependent enzyme, cystathionine β -synthase (see [Hyperhomocystinemias and Remethylation Disorders](#) previously). Cobalamin is acquired through dietary sources and must be appropriately transported and then undergoes a series of intracellular modifications. Thus impaired cellular cobalamin metabolism and other inherited defects in cobalamin transport or modification result in MMA (e.g., the deficient activity of cobalamin adenosyltransferase causes cobalamin B disease). Other inherited defects of cobalamin transport or modification may cause an isolated or a combined defect with homocystinuria (Carrillo et al., 1993; Manoli et al., 1993). Methylmalonic acid is detected in the blood, CSF, and urine of affected individuals. The disorder is typically identified through urine organic acid analysis after an abnormal NBS or in a clinically presenting neonate. The precursors of methylmalonyl-CoA are primarily isoleucine and valine but additionally include methionine, threonine, thymine, and odd-chain fatty acids.

There is a spectrum of severity of isolated MMA that ranges from severe, catastrophic newborn-onset disease to benign forms (Manoli et al., 1993). Patients presenting in the newborn period have a severe phenotype but may have a vitamin responsive form of the disorder (e.g., cobalamin A deficiency). Levels of homocysteine and vitamin B_{12} should always be assessed when elevated methylmalonic acid has been identified, and cobalamin should be provided empirically. The neonate appears well at birth but may rapidly progress as early as the 2nd or 3rd day of life to having problems with feeding and then develop vomiting, lethargy, and perhaps seizures. There may be tachypnea to compensate for metabolic acidosis. Crucial laboratory findings include metabolic acidosis with an increased anion gap, elevated lactate, elevated ketones, and elevated ammonia. The elevation of ammonia may be as high as that found in neonates presenting with early-onset UCDs, and

specialized biochemical genetic laboratory testing is required for diagnosis and should include a urine organic acid analysis and a plasma amino acid analysis, a plasma acylcarnitine profile, and a quantitative orotic acid level. Ketonuria is uncommon in newborns, and the physician must always consider an organic acidemia in an acutely ill newborn with ketosis. Other laboratory findings are thrombocytopenia, leukopenia, and anemia caused by effects of the metabolite on hematopoietic elements in bone marrow. Plasma amino acid analysis may reveal elevations of glycine and alanine. Elevations of C3-(methylmalonyl)-acylcarnitines may result in a secondary free carnitine deficiency caused by conjugation of accumulating metabolites, and so carnitine supplementation should be initiated (Baumgartner et al., 2014). Methylmalonic acid and other metabolites are detected in urine by organic acid analysis. The specific genetic diagnosis should be identified by DNA testing. Next-generation DNA sequencing panels are available, although results often take weeks to return. Most are inherited as autosomal recessive conditions, except for cobalamin X deficiency caused by a defect in *HCFC1*, a transcription factor that regulates the cobalamin C gene (Yu et al., 2013).

Rapid institution of empiric therapy may improve outcome, even in a patient who has presented clinically. Acute management protocols are available and should be administered in conjunction with a biochemical geneticist (Baumgartner et al., 2014). The treatment of acute metabolic decompensation includes cessation (for no more than 12–24 hours) of protein intake, empiric therapy with cobalamin, provision of high calories through protein-free enteral formula, and/or IV glucose at high concentration with IV intralipids, insulin, and carnitine. Some patients are responsive to pharmacologic doses of cobalamin, and 1 mg/day intramuscular hydroxocobalamin (preferred formulation) should be given as empiric therapy to a newborn presenting with hyperammonemia and acidosis (Baumgartner et al., 2014). Sodium bicarbonate should be used if indicated to correct acidosis. Dialysis is indicated for refractory hyperammonemia or acidosis. Additional therapies may include ammonia scavenger medications and carglumic acid, a stable analogue of the coactivator of the urea cycle that is depleted in MMA, causing the secondary hyperammonemia (Baumgartner et al., 2014). Chronic treatment includes a low natural-protein diet, an amino acid supplement lacking the MMA precursors, carnitine, and appropriate calories and fluid. Cobalamin is used chronically only when a specific and reproducible response is noted.

Most patients are now identified by NBS, although there are missed cases. False-positive NBS may result from maternal cobalamin deficiency. If the NBS and follow-up results are rapidly available, the outlook for the neonatal period may be improved. Episodes of decompensation will still occur. Patients who are particularly brittle or who develop renal failure receive either liver, kidney, or combined liver–kidney transplants. Long-term complications include basal ganglia stroke (which may occur in the newborn period), renal disease and failure, and pancreatitis (Baumgartner et al., 2014).

Propionic Acidemia

Propionic acidemia (PA) is due to a deficiency of propionyl-CoA carboxylase and is an autosomal recessive disorder. It was originally referred to as “ketotic hyperglycinemia,” because patients may have elevations of glycine as well as ketosis. Propionyl-CoA carboxylase is the enzymatic reaction just upstream of methylmalonyl-CoA mutase, and the precursors are identical (Fig. 22.4). The clinical

presentation and therapy of PA in the newborn period are similar to that of MMA. A biochemical geneticist with experience in the management of inborn errors should guide care and help guide diagnosis and the differentiation of MMA and PA from other possible disorders. Empiric therapy should be administered as described for MMA, with the provision of calories, IV glucose at high concentration with IV intralipid (once a disorder of fat metabolism has been ruled out), insulin (if needed), carnitine, cobalamin (for possible cobalamin-responsive MMA), and temporary cessation (no more than 12–24 hours from last intake) of protein. Hyperammonemia may be marked, and dialysis may be indicated. Ammonia-scavenging medications and carglumic acid may also be used, as for MMA (Chapman et al., 2012).

Elevated ammonia levels may be associated with CNS injury. Metabolic stroke, because of cell death in the absence of thrombosis or ischemia, may be seen in both MMA and PA and may result in damage to the basal ganglia. In MMA the globus pallidus is classically affected, while in PA the caudate and putamen are typically affected, resulting in severe choreoathetosis (Schreiber et al., 2012; Baumgartner et al., 2014). Chronic therapy consists of a low natural-protein diet, supplementation with metabolic formula lacking the MMA/PA precursors, carnitine, and adequate calories and micronutrients (Chapman et al., 2012). Biotin is a cofactor for the enzyme, but no case of biotin-responsive PA has been described; an empiric trial can be considered. Intestinal bacteria (*Propionibacterium* species) contribute to propionate production. Antimicrobial therapy with metronidazole has been used to lower propionate metabolites in acute illness and may be given as intermittent therapy to lower metabolites as part of chronic therapy. While not curative of the disorder, liver transplantation is being performed in individuals with early-onset PA with the goal of ameliorating long-term complications and enhancing quality of life (Chapman et al., 2012). The efficacy of liver transplant is unclear.

Outside of the newborn period, or in late-presenting individuals, episodes of metabolic decompensation are characterized by hyperammonemia, acidosis, and ketosis precipitated by excessive protein intake or more commonly by infection resulting in poor oral intake and protein catabolism. Families may use home urine ketone strips for monitoring so that early decompensation can be recognized and aggressive measures instituted to avoid further decompensation, as episodes can result in permanent neurologic damage. Affected individuals may exhibit developmental delay, seizures, cerebral atrophy, and EEG abnormalities (Schreiber et al., 2012). Other complications include optic atrophy, cardiomyopathy, and pancreatitis (Schreiber et al., 2012). Late-onset presentations include those with neurologic features only (Schreiber et al., 2012).

Diagnosis is made through urine organic acid analysis and confirmed by enzymatic and/or DNA testing. The acylcarnitine profile, on NBS or in plasma, will have elevated C3-(propionyl)-acylcarnitine, and urine organic acid analysis is required to distinguish between MMA and PA. In PA the urine has elevated 3-hydroxypropionic, propionyl glycine, and methylcitric acid but not methylmalonic acid. Both chronically and during acute decompensation, plasma ammonia may be mild to moderately elevated. The enzyme activity of propionyl-CoA carboxylase can be assayed in white blood cells or cultured skin fibroblasts. DNA testing may identify the numerous mutations that have been described in the two genes (*PCCA* and *PCCB*) that encode the subunits of this multimeric enzyme. Most patients are now identified by NBS, and the severe neonatal decompensation may be ameliorated if the results are rapidly available.

Isovaleric Acidemia

Isovaleric acidemia (IVA) is an autosomal recessive disorder caused by deficiency of the enzyme isovaleryl-CoA dehydrogenase. This is a defect in catabolism of the amino acid leucine. There are two major phenotypes, distinguished by the degree of enzyme deficiency and differing mutations: the acute form manifests as catastrophic disease in the newborn period, and the late-onset type is characterized by chronic, intermittent episodes of metabolic decompensation (Vockley and Ensenauer, 2006). In the acute form the infants become ill in the 1st week of life, similar to MMA and PA. Marked acidosis and ketosis suggest an organic acidemia, and urine organic acid analysis is required for diagnosis and shows elevations of isovalerylglycine and 3-hydroxyisovaleric acid. An elevated C5-(isovaleryl)-acylcarnitine value on plasma acylcarnitine analysis or on NBS is strongly suggestive of this diagnosis, although urine organic acid analysis is still required. DNA mutation analysis of the *IVD* gene is available. Another diagnostic clue is the characteristic “sweaty-feet, rancid cheese, or dirty socks” odor caused by isovaleric acid, which is detectable in blood and urine, especially during acidosis. Dialysis may be necessary if there is marked hyperammonemia. As for other organic acid disorders, acute treatment consists of protein restriction (for 12–24 hours) with the provision of calories, IV glucose at high concentration with IV intralipids, insulin (if necessary), carnitine, and sodium bicarbonate if indicated, followed by a protein-free formula to provide additional calories via nasogastric tube if enteral nutrition is tolerated and oral glycine (150 to 250 mg/kg per day) for known or suspected IVA and oral or IV carnitine supplementation (Vockley and Ensenauer, 2006). The excretion of isovaleric acid as the glycine conjugate is highly efficient, and improvement can occur rapidly with provision of glycine and other therapy.

In the chronic, intermittent form of IVA, patients have repeated episodes of metabolic decompensation precipitated by infection, other catabolic stress such as surgery, or excessive protein intake. These episodes may mimic Reye syndrome. The same therapeutic principles are applied as for the acute treatment of the neonatal disorder. Chronic therapy consists of a diet with low natural protein (limiting leucine to the amount required for growth), a leucine-free amino acid supplement to provide sufficient protein for growth, and glycine, which enhances isovalerylglycine production and reduces free isovaleric acid levels in body fluids (Vockley and Ensenauer, 2006). In addition, carnitine administration can augment the excretion of isovalerylcarnitine (Vockley and Ensenauer, 2006). Some patients who remain largely asymptomatic are ascertained through NBS. This form of IVA is associated with a specific mutation (p.A282V) in the *IVD* gene (Ensenauer et al., 2004). NBS and early institution of treatment can alter the prognosis of affected individuals (Grunert et al., 2012).

Multiple Carboxylase Deficiency

Two enzymatic defects, holocarboxylase synthetase deficiency and biotinidase deficiency, lead to deficiency of the four carboxylase enzymes, propionyl-CoA carboxylase, pyruvate carboxylase (PC), 3-methylcrotonyl-CoA carboxylase, and acetyl-CoA carboxylase, that require covalent linkage of the cofactor biotin to a lysine residue of the enzyme for normal activity (Wolf, 1993). Holocarboxylase synthase is the enzyme that catalyzes this covalent linkage, and a severe defect of this enzyme causes early-onset multiple carboxylase deficiency. The biotinidase enzyme regenerates biotin from the amide biocytin, formed by biotin and lysine. Biotinidase

deficiency causes late-onset multiple carboxylase deficiency because of the failure to recycle biotin. This condition typically does not manifest in the newborn period. High-dose biotin therapy is extremely efficacious in both conditions.

Infants with severe deficiency of holocarboxylase synthase become ill in the newborn period. They develop a marked metabolic acidosis with severe lactic acidosis and become encephalopathic. Administration of enteral biotin is life-saving, and empiric therapy should be administered if there is a concern for this disorder. In an affected neonate, administration of this vitamin results in a dramatic improvement in clinical and laboratory findings. As described for MMA, PA, and IVA, empiric management should include initial protein restriction, high calories, correction of acidosis, and empiric administration of cofactors and carnitine. After an initial period of empiric management, specific management should be based on the results of specialized biochemical testing. The goal is to have these results within 24 hours in order to provide the correct therapy. Evaluation and management should be guided by a biochemical geneticist familiar with the management of inborn errors.

The characteristic plasma acylcarnitine profile exhibits elevations of C3-(propionyl)-acylcarnitine and C5-OH-(3-hydroxyisovaleryl)-acylcarnitine and may be detected on NBS. Urine organic acid analysis identifies marked elevations of metabolites because of the deficiencies of pyruvate, propionyl-CoA, and 3-methylcrotonyl carboxylases. These include lactate, 3-hydroxypropionic acid and propionylglycine, and 3-methylcrotonylglycine, respectively. In most patients the defect is associated with decreased affinity of the holocarboxylase synthetase enzyme for biotin, and effective treatment requires between 10 mg and 100 mg of oral biotin per day. Long-term treatment may include dietary protein restriction and carnitine supplementation. The enzyme defect can be confirmed in cultured skin fibroblasts, or the diagnosis can be confirmed by DNA mutation analysis of the *BTD* or *HCLS* gene. Assay of individual carboxylases in white blood cells will show deficiency of all three carboxylases assayed, but this is not specific. The disorder is inherited as an autosomal recessive trait.

NBS also detects individuals with partial biotinidase deficiency (30% enzyme activity) who do not develop the severe symptoms of the profound deficiency. Enzyme analysis and mutation analysis distinguish these (Cowan et al., 2010; Wolf, 2010).

Late-onset multiple carboxylase deficiency caused by profound biotinidase deficiency may present as seizures and lactic acidosis and episodic decompensation. Long-term sequelae include hearing loss and optic atrophy. This disorder is effectively treated with biotin (10–20 mg/day), which prevents these long-term complications (Wolf, 1993). Effective NBS requires a specific biotinidase enzyme assay as it is not reliably detected by tandem mass spectrometry.

Glutaric Aciduria Type 1

Glutaric aciduria type 1 (GA1) is due to a deficiency of glutaryl-CoA dehydrogenase, an enzyme in the catabolic pathway of the amino acids lysine, hydroxylysine, and tryptophan (Boy et al., 2017). Unlike the organic acid disorders described previously that have systemic manifestations including hyperammonemia, lactic acidosis, ketosis, and bone marrow suppression, GA1 is termed a “cerebral” organic aciduria. In most instances the systemic manifestations of decompensation are not present, and GA1 does not have a catastrophic presentation in the newborn period that includes hyperammonemia and acidosis. The classic presentation is that of a child with normal growth and development in the first 6–18

months of life who experiences a metabolic stroke of the basal ganglia during illness, surgery, or another event that provokes catabolism (Kolker et al., 2006). Clinically affected children sustain irreversible bilateral damage to the caudate and putamen and, more rarely, the globus pallidus, structures of the basal ganglia that influence the control of voluntary movement, resulting in incapacitating dystonia and decreased life expectancy. Other affected individuals appear to have a slowly progressive course with hypotonia, dystonia, and dyskinesia in the first several years of life; these may have sustained early injury without a recognized encephalopathic illness. Remarkably, there is a vulnerable period for neurologic injury, and affected individuals who do not have injury in the first 6 years of life may have normal growth and development. This disorder is identified on NBS with elevations of C5DC-(glutaryl)-acylcarnitine, though some individuals termed “low excretors” may be missed (Boy et al., 2017). Chronic therapy includes a low natural-protein diet balanced with supplementation of a lysine-free, tryptophan-reduced, and arginine-containing formula, carnitine, and riboflavin (the enzyme cofactor that may show biochemical improvements in some cases). Acute emergency therapy includes protein restriction (for 12–24 hours) with the provision of calories as IV glucose at high concentrations with IV intralipids, insulin (if necessary), and carnitine, with supportive care from neurology or neurosurgery. These are critical to decreasing the incidence of devastating neurologic injury in affected individuals (Heringer et al., 2010; Boy et al., 2017).

GA1 may mimic nonaccidental trauma, as some individuals have subdural hematomata and retinal hemorrhages, independent of basal ganglia injury. Subdural hematomas may be identified in the investigation of crossing of percentiles for head circumference, a finding in GA1. Another finding that may prompt investigation for GA1 is increased fluid in the perisylvian fissures observed on brain computerized tomography or magnetic resonance imaging (MRI) (Boy et al., 2017). Manifestations in the newborn period include nonfamilial macrocephaly, increased fluid in the perisylvian fissures, and an abnormal NBS. Initial testing should include a plasma acylcarnitine profile, measurement of total and free carnitine, and a urine organic acid analysis.

Urine organic acid analysis will identify elevated glutaric acid and 3-hydroxyglutaric acid, though the latter compound, considered diagnostic of GA1, may be normal or near normal in a nondecompensated state in some individuals. Critically, these individuals, termed low excretors, are at no less risk of severe neurologic injury. The diagnosis may be confirmed by enzyme assay in fibroblasts or by DNA mutation analysis of the *GCDH* gene. NBS has resulted in a decrease in the incidence of neurologic injury in affected individuals (Heringer et al., 2010; Boy et al., 2017).

Fatty Acid Oxidation Disorders

FAODs are inborn errors of metabolism resulting in failure of β -oxidation within, or transport of fatty acids into, the mitochondria. There are at least 31 enzymes described. While short- and medium-chain fatty acids enter the mitochondria directly, carnitine is required for transport of long-chain fatty acids. Within the mitochondria the β -oxidation cycle will form acetyl-CoA and generate nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide (FADH₂), enabling electron transfer to the respiratory chain for adenosine triphosphate (ATP) generation. Acetyl-CoA is used as a substrate in the Krebs cycle to produce reducing equivalents for the electron transport chain (ETC) and ketone synthesis. FAODs lead to a deficit of energy production

and produce a wide range of clinical presentations from mild hypotonia in adults to sudden death (Rinaldo et al., 2002).

FAODs present at all ages and spare the CNS when in good metabolic control. Life-threatening phenotypes present in the first few days of life (typically after 24 to 48 hours of life) because of the severe catabolic state and enhanced breakdown of free fatty acids from adipose stores, often before NBS results being received. Signs include hypoglycemia, liver disease and liver failure, cardiac and skeletal myopathy, rhabdomyolysis, and retinal degeneration (Roe and Ding, 2001). The accumulation of long-chain acylcarnitine species has been suggested to be dysrhythmogenic and may be associated with cardiac dysfunction (Bonnet et al., 1999).

Currently, many countries diagnose most FAODs through NBS, but there is significant variability. The diagnosis is confirmed with a plasma acylcarnitine profile, total and free carnitine levels, and DNA testing. All disorders are autosomal recessive. Urine organic acid analysis and measurement of urine acylglycines should also be performed. If variants of uncertain significance are identified on DNA sequencing, leukocyte, fibroblast, or liver enzyme assays may be implemented to determine whether an individual is affected. False-positive NBSs are commonly due to carrier status. Many infants are now being identified with milder, and perhaps persistent, elevations of specific acylcarnitines but are not thought to be at significant risk for clinical disease, although long-term follow-up studies are needed to determine what, if any, risk is present for later-onset forms of these disorders, such as very long chain acyl-CoA dehydrogenase deficiency (VLCADD).

Treatment of FAOD shares many common features, and unique aspects will be reviewed in each section respectively. Treatment primarily is targeted at prolonged fasting avoidance to maintain a constant energy supply and prevent the use of fat for energy, together with a higher-carbohydrate, low-fat diet. Safe fasting periods for different age groups have been proposed: neonates until about 3 months of age should fast no longer than 3–4 hours, with this time gradually increasing through infancy (Spiekerkoetter et al., 2009b). IV fluids with 10% dextrose at 150% maintenance rate should be given when the patient is fasting for surgery.

For long-chain FAOD, supplementation with medium-chain triglyceride (MCT) oil is used to provide a substrate for β -oxidation and should be prescribed to provide 20%–25% of total calories (Spiekerkoetter et al., 2009b). Avoiding essential fatty acid deficiency requires supplementation with additional oils. MCT supplementation has been associated with a reversal of cardiomyopathy in carnitine acylcarnitine translocase deficiency (CACT) and VLCADD, although compliant VLCADD patients still had significant muscle weakness, muscle pain, or myoglobinuria (Pierre et al., 2007; Spiekerkoetter et al., 2009a; Pervaiz et al., 2011; Sharef et al., 2013).

Carnitine supplementation is controversial although secondary carnitine deficiency is common. Long-chain hydroxyl-acylcarnitines may exert toxicity by inducing arrhythmias, although mouse studies have been inconclusive (DaTorre et al., 1991).

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

Medium-chain acyl-CoA dehydrogenase deficiency (MCADD) is the most common FAOD with a frequency of approximately 1 in 20,000 births in northern European populations. Classic presentations occur in older infants during an infection, with poor oral intake, vomiting, dehydration, lethargy, hypoglycemia, seizures, and a presentation similar to Reye syndrome, leading to death from brain edema and hyperammonemia. Severe lethal presentations

will develop during the first days of life, and MCADD is a recognized cause of sudden infant death syndrome.

The initial presenting episode historically has a high mortality rate, but this has improved with NBS (Wilcken et al., 2007; Arnold et al., 2010). Plasma acylcarnitine profiles demonstrate increased levels of C6, C8, C10, and C10:1 values. Urine acylglycine analysis shows elevations of suberylglycine and hexanoylglycine. Sequence analysis of *ACADM* confirms the diagnosis with a common mutation, c.985A>G, seen frequently in those of northern European ancestry. Treatment focuses on avoiding prolonged fasting, especially during intercurrent illness, and carnitine supplementation if necessary.

Very Long Chain Acyl-CoA Dehydrogenase Deficiency

VLCADD has been estimated to affect between 1 in 100,000 to 1 in 120,000 individuals, but prevalence may be as high as 1 in 42,500 (Zytkovicz et al., 2001; Chace et al., 2002; Spiekerkoetter et al., 2003; Wilcken et al., 2003). VLCADD presents with variable phenotypes ranging from severe cardiomyopathy that may result in death in the first few days of life to recurrent hypoketotic hypoglycemia or to later-onset presentations with myopathy and/or rhabdomyolysis in adolescence or adulthood (Bertrand et al., 1993; Bonnet et al., 1998; de Lonlay-Debeney et al., 1998; Bonnet et al., 1999; Kluge et al., 2003; Hoffman et al., 2006). Cardiomyopathy and arrhythmias have been reported in a high proportion of cases presenting at less than 6 years in a country without newborn screening (Baruteau et al., 2014).

Most patients with VLCADD are detected through NBS but present a significant challenge in that a large number of individuals appear to have mild or perhaps benign DNA variants and normal follow-up plasma acylcarnitine profiles. Many of these cases will have a single heterozygous mutation and so appear to be unaffected carriers. Others may have two compound heterozygous mutations but have a reduced clinical risk of symptoms. Plasma acylcarnitines show a pattern of elevations of C14:1-, C14-, C16:1-, and C16-acylcarnitines levels with low secondary free carnitine levels in some infants. With an acute metabolic decompensation, urine organic acid analysis may demonstrate dicarboxylic aciduria. Confirmation by sequencing and deletion/duplication analysis of *ACADVL* is recommended. Functional enzyme assay or fibroblast acylcarnitine probe analysis may be helpful to determine treatment when a single heterozygous mutation is found, novel uncharacterized variants are found, and/or there are persistent elevations of acylcarnitines inconsistent with the genotype (Pena et al., 2016).

Treatment follows the general principles for long-chain FAOD treatment, consisting of fasting avoidance, dietary fat restriction, MCT supplementation, and carnitine supplementation if necessary. Infants should discontinue breastfeeding because of the high fat content in breast milk, with implementation of an MCT-containing formula (Spiekerkoetter et al., 2009b). Treatment of milder forms of VLCADD may include supplementation of breastfeeding with an MCT-containing formula.

Short-Chain Acyl-CoA Dehydrogenase Deficiency

Short-chain acyl-CoA dehydrogenase deficiency (SCADD) is diagnosed through the detection of elevations of C4-acylcarnitine, urinary ethylmalonic acid, and butyrylglycine. Prior reports found decreased SCAD enzyme activity to be associated with failure to thrive, poor feeding, hypotonia, and seizures. Subsequently, up to 14% of the

normal population has been found compound heterozygous or homozygous for two common polymorphisms (c.511C>T and c.625G>A) with the biochemical abnormalities of SCADD (Pedersen et al., 2008). Currently, most infants with SCADD are detected on NBS and remain clinically asymptomatic leading many to consider this a benign condition (Gallant et al., 2012). The need for treatment, carnitine or riboflavin supplementation, or management during illness is unclear (Wolfe et al., 1993).

Long-Chain 3-Hydroxy Acyl-CoA Dehydrogenase Deficiency and Trifunctional Protein Deficiency

The mitochondrial trifunctional protein complex of four alpha and four beta subunits comprises three enzymes: long-chain enoyl-CoA hydratase, long-chain 3-hydroxy acyl-CoA dehydrogenase, and 3-ketoacyl-CoA thiolase. Long-chain 3-hydroxy acyl-CoA dehydrogenase deficiency (LCHADD) occurs when there is only reduced dehydrogenase activity because of mutations in the *HADHA* gene, while trifunctional protein deficiency (TFP) results from mutations in either the *HADHA* or *HADHB* gene and in deficient activity of all three enzymes. The prevalence of LCHADD is approximately 1 in 110,000 while TFP is much rarer (Das et al., 2006). The most severe forms of LCHADD or TFP present with a rapidly progressive neonatal cardiomyopathy (Spiekerkoetter et al., 2009a; Sperk et al., 2010). Infants may later develop recurrent hypoketotic hypoglycemia with acute catabolic illness resulting in liver dysfunction (a Reye-like syndrome), cardiomyopathy, myopathy, and rhabdomyolysis. Sixty-five percent of surviving individuals with LCHADD or TFP experience skeletal myopathy, 21% develop a slowly progressing peripheral neuropathy, and 43% have pigmentary retinopathy (Spiekerkoetter et al., 2009a). Some patients may have severe liver disease with fibrosis in addition to necrosis and steatosis. Older children, adolescents, and adults may develop recurrent rhabdomyolysis during illness.

Heterozygous mothers may rarely develop either acute fatty liver of pregnancy or hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome) when carrying a child with LCHADD (Ibdah et al., 1999).

Diagnosis is made through the demonstration of elevations of C16:1-OH-, C16-OH-, C18:1-OH-, and C18-OH-acylcarnitines levels and the demonstration of longer-chain 3-hydroxydicarboxylic acids on urine organic acid analysis. Enzymatic diagnosis can be made in lymphocytes or in skin fibroblasts, but a combination of clinical biochemical abnormalities and *HADHA* or *HADHB* mutation analysis is often sufficient. The majority of moderate-to-severe cases are diagnosed by NBS. Follow-up of cases diagnosed on NBS demonstrates improved growth and development, but NBS does not completely prevent morbidity and mortality, especially in TFP, which has poorer survival (Sander et al., 2005; Spiekerkoetter et al., 2009a; Sperk et al., 2010; Wilcken, 2010).

Treatment of LCHADD and TFP involves avoidance of prolonged fasting, dietary fat restriction, and MCT supplementation. A low-fat diet and MCT supplementation decrease plasma hydroxyl acylcarnitine levels, and most LCHADD patients remain healthy without metabolic decompensation but still require supplementation with essential fatty acids and fat-soluble vitamins (Gillingham et al., 2003).

Primary Carnitine Transporter Deficiency

Carnitine is essential for long-chain fatty acid transport across the mitochondrial inner membrane. This is dependent upon a

sodium-dependent carnitine transporter, two transferases that covalently link and then remove carnitine to the long-chain fatty acid, and a translocase.

Carnitine transporter deficiency (CTD, primary carnitine deficiency, carnitine uptake defect) is characterized by hypoketotic hypoglycemia, hyperammonemia, liver dysfunction, cardiomyopathy, and skeletal hypotonia. Neonatal presentations are not common. In some older patients, cardiomyopathy may be the presenting sign. Profoundly low plasma total and free carnitine levels (typically $<10 \mu\text{mol/L}$ in plasma) are found. False-positive NBS for low free carnitine levels may be due to neonatal nutritional deficiency or secondary to low maternal plasma carnitine levels from either a dietary restriction (e.g., vegan diet) or previously unrecognized maternal primary carnitine deficiency. Measurement of maternal total and free carnitine levels is often necessary when performing follow-up testing of an abnormal NBS. Women with true maternal primary carnitine deficiency may be apparently asymptomatic at diagnosis. Diagnostic confirmation is through DNA sequencing of *SLC22A5* or analysis of fibroblast carnitine uptake (El-Hattab, 1993).

Treatment of primary carnitine deficiency involves supplementation of carnitine at 100 to 200 mg/kg per day to maintain normal carnitine levels. Treatment is successful in preventing or reversing symptoms but is dependent upon compliance.

Carnitine Palmitoyltransferase Type I Deficiency

Carnitine palmitoyltransferase type I (CPTI) covalently links long-chain fatty acids to carnitine. CPTI deficiency will present in early childhood with hypoketotic hypoglycemia and liver dysfunction, less commonly as an adult-onset skeletal myopathy, and only with rare presentations of neonatal hypoglycemia (Bennett and Santani, 1993). Cardiomyopathy is typically not seen, although renal tubular acidosis has been reported (Bonnefont et al., 2004). Diagnostic laboratory findings include elevated total and free plasma carnitine levels, while NBS additionally uses a C0/(C16+C18) ratio to improve specificity. Confirmatory testing will demonstrate mutations in the *CPT1A* gene or through enzyme activity in skin fibroblasts. A common *CPT1A* variant, c.1436C>T (p.P479L), has been identified in the Arctic populations of the Inuit, Alaskan Native, Canadian First Nation, and Hutterite and has been associated with higher infant mortality and impaired fasting intolerance in these populations (Collins et al., 2010; Gillingham et al., 2011; Clemente et al., 2014). Treatment involves fasting avoidance, low-fat diet, and MCT supplementation and results in a normal outcome, although some suffer neurologic impairment from repeated episodes of metabolic decompensation (Bonnefont et al., 2004; Longo et al., 2006).

Carnitine Acylcarnitine Translocase Deficiency

CACT is one of the more severe FAODs, and the most common presentation is ventricular dysrhythmia and sudden neonatal death (Yang et al., 2001; Wilcken, 2010). Symptoms include hypoglycemia, vomiting, gastroesophageal reflux, and mild chronic hyperammonemia, as well as severe skeletal myopathy and mild hypertrophic cardiomyopathy. Early diagnosis and treatment can be beneficial, although significant morbidity includes profound developmental delay, seizures, and other complications despite NBS (Pierre et al., 2007; Al-Sannaa and Cheriyan, 2010; Spiekerkoetter, 2010; Wilcken, 2010). Milder disease is associated with higher residual enzyme activity (Rubio-Gozalbo et al., 2004).

Individuals will have elevated C16-, C16:1-, C18-, and C18:1-acylcarnitine levels with low free carnitine levels on diagnostic testing and NBS. DNA sequencing of *SLC25A20* will confirm disease. Treatment includes fasting avoidance with a low-fat, high-carbohydrate formula, MCT supplementation, and carnitine.

Carnitine Palmitoyltransferase Type II Deficiency

Carnitine palmitoyltransferase type II deficiency (CPTII) results in elevations of C16- and C18:1-acylcarnitines in NBS as found with CACT deficiency; DNA testing is required for diagnosis; treatment depends on severity. Children with the severe form of CPTII deficiency may have congenital anomalies including renal cysts, dysmorphic facies, and brain malformations and may present with hypotonia, cardiomyopathy, arrhythmias, and seizures within the newborn period (Albers et al., 2001). The later-onset form of CPTII deficiency is much more common and presents in the second or third decade of life with exercise intolerance or rhabdomyolysis (Longo et al., 2006). Confirmatory sequencing of the gene *CPT2* will reveal mutations (Wieser et al., 2003).

Multiple Acyl-CoA Dehydrogenase Deficiency

Multiple acyl-CoA dehydrogenase deficiency (MADD; also called *glutaric acidemia type 2*) is the result of a defect of electron transfer from multiple acyl-CoA dehydrogenases to the mitochondrial ETC. Each acyl-CoA dehydrogenase enzyme binds electron transfer flavoprotein (ETF). ETF accepts electrons from the FADH_2 cofactor in the oxidative dehydrogenation reactions and is made up of three subunits. Mutations in the genes for the three subunits, *ETFA*, *ETFB*, and *ETFDH*, will interfere with electron transfer from ETF to coenzyme Q10 within the mitochondria. Riboflavin (an FADH_2 component) deficiency or deficient riboflavin transport may show a similar presentation—a riboflavin-responsive form of MADD has been described. Because of the multiple dehydrogenase enzymes involved there will be elevations of metabolites from short-, medium-, and long-chain fatty acids and amino acid metabolism.

MADD may present in three major ways. The first two present in the newborn period, with or without congenital anomalies, and the third is a later-onset type. Neonatal MADD presents with metabolic acidosis, hypoketotic hypoglycemia, and often hypertrophic cardiomyopathy. Those with congenital malformations may have enlarged polycystic kidneys, rocker-bottom feet, defects of the inferior abdominal musculature, and hypospadias and chordee. Hypotonia, cerebral cortical dysplasia, and gliosis have been reported, and dysmorphic facies may include telecanthus, malformed ears, macrocephaly, large anterior fontanel, high forehead, and a flat nasal bridge (Wilson et al., 1989). Older patients with the later-onset MADD do not have congenital malformations but have a lifelong risk of acute intermittent episodes with vomiting, dehydration, hypoketotic hypoglycemia, and acidosis. In some there may be hepatomegaly and muscle disease.

Many infants do not survive beyond the first few weeks or months of life because of rapidly progressing cardiomyopathy. In individuals identified through NBS and in whom treatment is initiated early, acute, life-threatening events or sudden death may still occur (Angle and Burton, 2008; Singla et al., 2008).

Diagnosis of MADD is suspected due to the combination of increased anion gap lactic acidosis, hypoketotic hypoglycemia, and hyperammonemia. They may have an odor of isovaleric acid. Increased serum transaminases and prolongations of prothrombin

time and partial thromboplastin time suggest liver dysfunction. Diagnostic testing should include plasma acylcarnitines with elevations of C4 and C5 acylcarnitines (which are the primary analytes on NBS), but medium- and long-chain acylcarnitines may also be present (i.e., C8-, C10:1-, C12-, C14-, C14:1-, C16-, C16:1-, C18-, C18:1-, C16-OH-, C16:1-OH-, C18-OH-, and C18:1-OH-acylcarnitines). Urine organic acid analysis will show elevations of ethylmalonic acid, glutaric acid, and 3-hydroxyisovalerate in addition to lactic acid, medium- and long-chain dicarboxylic acids, the glycine conjugates isovalerylglycine, isobutyrylglycine, and 2-methylbutyrylglycine. Ketone bodies, including acetoacetic acid and 3-hydroxybutyric acids, are minimal or undetectable. Generalized aminoaciduria will reflect impaired renal tubular function. DNA sequencing of *ETFA*, *ETFB*, and *ETFDH* will confirm the diagnosis.

Treatment of MADD includes a low-protein and low-fat diet, fasting avoidance, and supplementation with carnitine, riboflavin, and glycine. Individualized metabolic formulas often have to be designed to meet nutritional goals. Individuals at least heterozygous for common *ETFDH* mutations confer a milder riboflavin-responsive phenotype with some cases of complete correction of clinical and biochemical parameters after riboflavin treatment (Olsen et al., 2007). Acute decompensation should be treated with IV glucose and carnitine to restore anabolism with close monitoring of cardiac, hepatic, and renal function.

Ketone Metabolism Disorders

Disorders of ketone metabolism result from the inability to use ketone bodies, 3-hydroxybutyric acid and acetoacetic acid, for energy generation. Each cycle of the fatty acid β -oxidation generates a single acetyl-CoA. This acetyl-CoA has to be converted to acetoacetic acid by mitochondrial acetoacetyl-CoA thiolase, 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) synthase, and then HMG-CoA lyase. Acetoacetic acid and 3-hydroxybutyric acid are transported out of liver mitochondria and hepatocytes into blood to be used by other tissues, especially the brain and heart.

Patients with mitochondrial acetoacetyl-CoA thiolase deficiency (β -ketothiolase or 3-oxothiolase deficiency) have a metabolic acidosis associated with excess ketosis. Most commonly presenting in children around 15 months of age, cases are reported as early as 3 and 4 days of age with lethargy, metabolic ketoacidosis, and an elevated anion gap (Fukao et al., 2001; Cubillo Serna et al., 2007). The clinical presentation varies from severe, acute metabolic decompensation in infants to asymptomatic adults. The episodes are intermittent, are typically associated with a catabolic stressor or a high dietary protein intake, and have been associated with mild hyperketotic hypoglycemia and liver dysfunction, without hyperammonemia. Cardiomyopathy is rare. Plasma acylcarnitines and NBS will demonstrate elevations of C5-OH- and C5:1-acylcarnitines. Urine organic acid analysis demonstrates significant elevations of lactate and ketone bodies and a specific pattern of elevations of 2-methylacetoacetate, 2-methyl-3-hydroxybutyrate, and tiglylglycine. Older children and adults have ketoacidosis while others have remained asymptomatic. Diagnosis is confirmed by DNA sequence analysis of the *ACAT1* gene looking for mutations in this autosomal recessive disorder. Acute treatment involves IV glucose and bicarbonate to correct metabolic acidosis, which is often severe, while long-term therapy includes mild protein restriction, avoidance of fasting, and prompt attention to any intercurrent illness or catabolic stressor, as treatment and avoidance of severe ketoacidosis may lead to normal development.

The most severe disorder of ketone metabolism is the last step in synthesis of acetoacetate from HMG-CoA via the HMG-CoA lyase enzyme. Neonates present as early as 3 days of life with an often-catastrophic illness characterized by vomiting, lethargy, hypoketotic hypoglycemia, metabolic acidosis, hyperammonemia, elevated transaminases, hepatomegaly, seizures, and coma. Urine organic acid analysis reveals 3-hydroxy-3-methylglutaric acid, 3-methylglutaconic acid, and 3-hydroxyisovaleric acid in a specific diagnostic pattern with elevations of C5-OH- and C6-DC-acylcarnitines on plasma acylcarnitine analysis and NBS. Levels of acetoacetic acid and 3-hydroxybutyric acid may be unexpectedly low. Lactate values may be elevated during the acute metabolic decompensation.

An autosomal recessive disorder, the HMG-CoA lyase deficiency is confirmed by mutation analysis of the *HMGCL* gene. Acute treatment of the episode consists of administration of IV rehydration and administration of glucose and bicarbonate, to correct metabolic acidosis. Long-term treatment consists of avoiding prolonged fasting, a low-protein and high-carbohydrate diet, and carnitine supplementation (Gibson et al., 1988).

Succinyl-CoA 3-ketoacid-CoA transferase deficiency results from the failure of extrahepatic tissues to convert acetoacetate back to acetoacetyl-CoA. This is required for hydrolysis to acetyl-CoA for final metabolism in the TCA cycle. Affected patients have a persistent ketosis with intermittent ketoacidosis that does not resolve, even postprandially. Affected newborns often present in the 1st week of life with severe ketosis, lactic acidosis, hypoglycemia, and coma, and many do not survive (Fukao et al., 2014). Elevated acetoacetate and 3-hydroxybutyrate levels are almost always present in blood and urine. Therapy focuses on fasting avoidance, which can cause profound acidosis and ketosis, and IV fluids, glucose, and sodium bicarbonate during crisis. Enzyme analysis in fibroblasts is available, but DNA sequencing of the *OXCT1* gene will confirm the diagnosis in this autosomal recessive disorder. Milder forms do exist, and patients may have nonketotic periods.

Primary Lactic Acidosis

Congenital lactic acidosis (CLA) is due to a severe disorder of energy metabolism. This can be caused by one of multiple diseases, including those in which lactate and pyruvate metabolism are impaired because of a primary defect in the mitochondrial ETC or the tricarboxylic acid (TCA) cycle. These disorders affect pyruvate metabolism, which, in turn, affects lactate. The majority of neonates presenting with CLA have defects of the mitochondrial ETC or the PDH complex or PC deficiency. Inborn errors of the TCA cycle are much rarer but should be considered in the differential diagnosis. A recently described autosomal recessive disorder of metabolism of the amino acid valine, short-chain enoyl-CoA hydratase deficiency because of mutations in the *ECHS1* gene, appears to cause a secondary inhibition of PDH and can present with refractory CLA with a Leigh disease-like presentation, neurodegeneration, and neonatal death (Ferdinandusse et al., 2015).

Some patients with CLA present with overwhelming lactic acidosis in the neonatal period. In others, lactate may be elevated only in CSF. This “cerebral” lactic acidosis may present more indolently. When blood lactate is elevated, the ratio of blood lactate to pyruvate can help narrow the differential diagnosis. The ratio is low to normal (10 to 20) in PDH deficiency, may be modestly elevated in PC type B deficiency (see later), but may be greatly elevated (>25) in an ETC defect. This ratio reflects the oxidation–reduction state of the mitochondria. When calculating this

it is important to ensure the units of the two compounds are the same. These conditions are not identified through NBS, and patients will present symptomatically unless there has been a prior affected family member such as an older affected sibling.

Pyruvate Dehydrogenase Complex Deficiency

The PDH complex converts pyruvate, which is derived from the catabolism of glucose, to acetyl-CoA, which enters the TCA cycle at citrate synthase. Severe PDH deficiency may manifest in the neonatal period with profound lactic acidosis and a low to normal lactate-to-pyruvate ratio. Patients may have moderately elevated plasma ammonia and congenital brain anomalies including an absent or underdeveloped corpus callosum and heterotopias. They are hypotonic and may require mechanical ventilation. The prognosis is poor, even with early recognition and intervention. Importantly, the high concentration dextrose-containing IV and enteral empiric therapy that may be life-saving for a child with a possible organic aciduria or urea cycle defect exacerbates the lactic acidosis in the neonate with PDH deficiency or other mitochondrial energy metabolism disorders. This worsening may suggest a primary energy metabolism disorder in the neonate. A possible diagnosis of PDH deficiency is inferred from the patient presentation, the clinical course, and the results of routine and specialized biochemical laboratory testing. Alanine will likely be elevated on plasma amino acid analysis, and TCA cycle intermediates may be elevated in the urine organic acid analysis. There is no specific diagnostic compound that identifies this disorder. The diagnosis is made through abnormal enzyme analysis in skin fibroblasts or white blood cells and/or by DNA testing. The majority of individuals have a mutation in the *PDHA1* gene, which encodes the E1- α subunit of the PDH enzyme complex. This is an X-linked dominant condition, and both males and females are affected (Patel et al., 2012).

PDH is a large, multisubunit complex. It contains three enzymatic subunits and several regulatory subunits, including a phosphatase and a kinase. The first enzymatic step is a decarboxylation reaction catalyzed by a heterodimeric system consisting of the E1- α subunit and E1- β . All other subunits, including E1- β , result in autosomal recessive inheritance. Defects in all the known genes have been reported, and DNA sequencing is available, but mutations in *PDHA1* account for 80% of cases of PDH deficiency.

The majority of patients are indolent on clinical presentation with developmental delay and an MRI indicative of Leigh disease. This group of patients often responds well biochemically to a high-fat and low-carbohydrate, or ketogenic, diet. Fat, as acetyl-CoA, enters the energy pathway after the block, whereas glucose must traverse the defective PDH enzymatic reaction to provide energy.

Defects of the PDH complex because of defects in the two other enzyme subunits, the activating and deactivating enzymes and a structural protein that binds one subunit (E3 binding protein), are rarer. These usually result in chronic psychomotor retardation syndrome in late infancy and childhood. Deficiency of the E3 subunit of the PDH complex has pleiotropic biochemical effects, because the subunit is a component of two other dehydrogenase complexes: the BCKAD complex and the α -ketoglutarate dehydrogenase complex of the TCA cycle. Therefore these patients have elevated BCAAs as in MSUD, which is due to BCKAD deficiency, as well as elevated TCA cycle metabolites because of α -ketoglutarate dehydrogenase complex deficiency. Most patients with E3 deficiency present after the newborn period and have

progressive neurodegenerative disease. The key laboratory findings are the elevation of lactic acid in blood with elevated pyruvate and a low lactate-to-pyruvate ratio, elevated BCAAs on plasma amino acid analysis, and detection of α -ketoglutarate and BCAA metabolites in urine organic acid analysis. PDH phosphatase deficiency is a rare cause of CLA. Apart from E3 deficiency, defects in the PDH complex are responsive to the ketogenic diet.

In addition to E3 deficiency there is another class of defects that affects PDH and other enzyme complexes, including BCKAD and α -ketoglutarate dehydrogenase complex, because of the requirement for lipoate in these and the complex synthesis of lipoate. Defects in eight genes encoding proteins required for lipoate synthesis have been reported, and these may present as CLA (Tort et al., 2016). Symptoms are variable and may be characteristic of the specific genetic defect. In an early-onset presentation, symptoms can include seizures, encephalopathy, and cardiomyopathy (Tort et al., 2016).

Pyruvate Carboxylase Deficiency

PC is involved in gluconeogenesis and adds bicarbonate to pyruvate to form oxaloacetate, a compound also involved in replenishing intermediates of the TCA cycle. PC is one of the four carboxylases that are biotin-requiring enzymes. There are three main types of PC deficiency. Type A is characterized by lactic acidosis in the newborn period and delayed development, and the disease has a chronic course. The catastrophic form of the disorder is type B where the neonate is acutely ill in the first week of life, is encephalopathic, and develops severe metabolic acidosis with lactic acidosis and hyperammonemia. The mortality rate in this form of PC deficiency is high. Type C is considered intermittent and benign (Wang and De Vivo, 1993).

Most patients with the type B form of PC deficiency have been of French or English background. The blood lactate-to-pyruvate ratio is normal in type A as both lactate and pyruvate are comparably elevated, while patients with type B often have an elevated lactate-to-pyruvate ratio. Because oxaloacetate produces aspartate, which then combines with citrulline to create argininosuccinate through the urea cycle, PC deficiency leads to elevations of plasma citrulline and plasma ammonia. Although PC is an important enzyme in gluconeogenesis, hypoglycemia is not common. The liver may be enlarged. The prognosis is poor. Enzyme testing may be performed in white blood cells or fibroblasts. DNA mutational analysis may also be performed for diagnosis.

Electron Transport Chain Defects

Oxidative phosphorylation results in the generation of ATP and is the central process performed by mitochondria. Genetic defects affecting the tightly coupled and regulated process of ATP generation may have profound effects on one or more organ systems. Derivatives of nutrients such as pyruvate and fatty acids are converted to carbon dioxide in mitochondria. The energy derived from this is harnessed by allowing the reducing equivalents (as NADH or FADH₂, which are derived from such metabolism) to combine with oxygen to form water and, in the process the synthesis of ATP, is coupled to the flow of electrons down the ETC.

The important components in the mitochondrial respiratory chain are complex I (NADH dehydrogenase), complex II (ETF dehydrogenase), complex III (cytochromes *b*, *c*₁), and the terminal complex in this chain, complex IV (cytochrome *c* oxidase). In addition, there is a complex V (ATP synthetase) and an adenine

nucleotide translocase that permit transport of adenosine diphosphate into, and ATP out of, the mitochondria. Complex II is involved primarily in fatty acid oxidation and oxidation of succinate derived from the TCA cycle, because the reducing equivalents extracted from fatty acids, glutaric acid, and succinate flow from ETF into complex II. Early understanding of the molecular mechanisms that produce ETC disturbances concerned those attributed to mutations of mitochondrial DNA (mtDNA—a small circular DNA molecule located within the mitochondria) genes, although in recent years multiple new disorders that effect the ETC caused by nuclear (chromosomal) encoded genes have been identified through DNA sequencing. mtDNA is important in production of the subunits of each respiratory chain complex as at least one subunit is encoded by the mtDNA except for complex II. CLA caused by defects in ETC components can be due to either nuclear or mtDNA encoded subunits, which is an important factor in genetic counseling of families of affected children. In addition to the structural components of a respiratory chain complex, defects in genes encoding proteins responsible for the assembly of the protein subunits into functional complexes can also cause lactic acidosis. Nuclear DNA encodes these assembly proteins, and defects in more than 1000 genes can result in ETC deficiency (Parikh et al., 2015).

The relationship between phenotype and a specific mtDNA mutation is not straightforward, due, at least in part, to heteroplasmy (the proportion of mutant and nonmutant mtDNA molecules within each cell, each of which contain many mitochondria that also each contain multiple copies of mtDNA). Mitochondria and their mtDNA are inherited solely from the mother. Random segregation of mitochondria having greater or fewer mtDNA mutations as oocytes are formed leads to a “bottleneck effect” in which the fetus has a higher concentration of cells with mutant mtDNA than the mother, who may have little or no mutant mtDNA detectable in blood. Often there is a different proportion of defective mitochondria in different cells and different tissues, and, crucially, there is a tissue-specific “threshold effect”; that is, a certain proportion of mutant mtDNA molecules must be present to have clinical consequences in a given tissue (Wallace et al., 1988; Parikh et al., 2015).

The disorders caused by nuclear DNA gene mutations are most often autosomal recessive, and they comprise the majority of ETC disease presenting in neonates and infants, with a minority resulting from mtDNA gene mutations with a maternal inheritance pattern. With the exception of neurogenic muscle weakness, ataxia, and retinitis pigmentosa (NARP, caused by a mutation at position 8993 of the mtDNA), only a minority of diseases caused by mtDNA mutations manifest in the newborn period (Wong, 2007). Other examples of syndromes caused by mtDNA mutations are MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes, mtDNA position 3243) and MERRF (myoclonic epilepsy with ragged-red fibers, position 8344) syndromes, Leber hereditary optic neuropathy (Wallace et al., 1988), and sporadic deletion–duplication syndromes such as Pearson marrow–pancreas syndrome (Di Donato, 2009). Important mitochondrial energy metabolism disorders that affect infants include CLA, the most dramatic form, with presentation often in the first few days of life during which there is marked lactic acidosis (Carrozzo et al., 2007; Gibson et al., 2008); subacute necrotizing encephalomyopathy or Leigh disease that classically presents at later than 3 months of age but can present earlier; Alpers disease presenting with seizures and liver disease; benign infantile mitochondrial myopathy, cardiomyopathy, or both; lethal infantile mitochondrial disease; lethal infantile

cardiomyopathy; and Pearson syndrome. The hallmarks of mitochondrial disease are often multisystem involvement and lactic acidosis, but involvement of only one organ system and the absence of lactic acidosis do not exclude it.

Important classes of mitochondrial disorders include nuclear encoded mtDNA depletion syndromes resulting from defects in mtDNA replication component proteins or in the availability of nucleotides for DNA replication, which may include fatal hepatopathy (El-Hattab and Scaglia, 2013; Mayr et al., 2015). Another class is the defects in lipoate synthesis, including those of iron–sulfur protein synthesis (Tort et al., 2016). A potentially treatable class is that of coenzyme Q10 biosynthesis diagnosed by DNA testing of nuclear genes or by coenzyme Q10 levels in muscle. This includes a severe infantile multisystem disease, and it is important to identify these defects as they are one of the few classes of mitochondrial disorders in which administration of coenzyme Q10 may be effective (Quinzii and Hirano, 2011).

The diagnostic tools include measurement of plasma lactate and pyruvate and analysis of urine organic and plasma amino acids. CSF lactate may be measured by lumbar puncture and by magnetic resonance spectroscopy during MRI. The current availability of mtDNA sequencing panels and whole exome sequencing with full sequencing of the mitochondrial genome has decreased the use of muscle biopsy. However, histologic analysis of muscle tissue by light and electron microscopy and mitochondrial respiratory chain complex assay on either fresh (preferred, but infrequently available) or flash-frozen tissue may be of aid in diagnosis. In many cases however, DNA sequencing has replaced muscle biopsy as a first-line test for suspected mitochondrial disease (Parikh et al., 2015). In fatal cases, rapid (metabolic) autopsy and proper preservation of tissue specimens are essential if functional assays are to be performed. DNA testing can also be performed on tissues.

Benign Infantile Mitochondrial Myopathy, Cardiomyopathy, or Both

Benign infantile mitochondrial myopathy is associated with congenital hypotonia and weakness at birth, feeding difficulties, respiratory difficulties, and lactic acidosis. In this poorly understood disorder, only skeletal muscle appears to be affected, and histochemical analyses show a cytochrome *c* oxidase deficiency that returns to normal levels after 1 to 3 years of age. A nuclear DNA mutation in a gene-encoding fetal isoform of an ETC polypeptide specific for muscle oxidative phosphorylation was hypothesized to be the cause of this. A developmental switch from the defective fetal gene to the adult form may be responsible for the gradual improvement. It was thought to be the only example of a developmental defect in oxidative phosphorylation that is probably nuclear encoded and in which the treatment is supportive during the early newborn period to prevent death from respiratory disease. A study suggested the etiology may be due to a maternally inherited homoplasmic m.14674T>C or T>G mitochondrial tRNA^{Glu} mutation or may be due to mutations in the nuclear gene *TMRU* (Horvath et al., 2009; Uusimaa et al., 2011).

The form also associated with cardiomyopathy may be a variant of the benign isolated myopathy and involves striated muscle in both skeletal and cardiac muscle. It manifests in the newborn period with lactic acidosis and a cardiomyopathy that improves during the first year of life. The exact gene defect is unknown. More attention must be paid to these two disease entities because with early optimal medical care affected infants may have an excellent prognosis.

Lethal Infantile Mitochondrial Disease

Infants with lethal infantile mitochondrial disease are severely ill in the first few days or weeks of life or in the extended newborn period. They exhibit hypotonia, muscle weakness, failure to thrive, and severe lactic acidosis. Death often occurs by 6 months of age and almost always is associated with overwhelming lactic acidosis. Skeletal muscle shows lipid and glycogen accumulation and abnormally shaped mitochondria on electron microscopic examination. Hepatic dysfunction may be a prominent finding in these patients. Generalized proximal renal tubular dysfunction may occur, leading to renal Fanconi syndrome. The ETC defects reported in these patients include defects in complexes I, III, and IV. Genes responsible for combined ETC defects continue to be identified (Mayr et al., 2015).

Leigh Disease: Subacute Necrotizing Encephalomyelopathy

Leigh disease is a progressive neurodegenerative disorder with severe hypotonia, seizures, extrapyramidal movement disorder, optic atrophy, and defects in automatic ventilation or respiratory control (Baertling et al., 2014). Generally, disease onset is outside of the neonatal period, but symptoms may be evident in the first months of life. There are more than 70 genetic defects known to be associated with Leigh disease (Gerards et al., 2016). These include defects in the PDH complex, ETC structural proteins, assembly factors of individual ETC complexes, coenzyme Q10 biosynthesis, biotinidase, and others. MRI characteristically shows bilateral symmetrical T2-weighted hyperintense lesions in the basal ganglia. One disorder with features of Leigh disease is biotin–thiamine-responsive basal ganglia disease caused by *SLC19A3* deficiency, and empiric biotin and thiamine should be trialed (Baertling et al., 2014).

Clinical findings in infants with Leigh disease include optic atrophy, ophthalmoplegia, nystagmus, respiratory abnormalities, ataxia, hypotonia, spasticity, seizures, developmental delay, psychomotor retardation, myopathy, and renal tubular dysfunction. Some patients may manifest hypertrophic cardiomyopathy, liver dysfunction, and microcephaly. The neuropathologic lesions include demyelination, gliosis, necrosis, relative neuronal sparing, and capillary proliferation in specific brain lesions.

Pearson Syndrome

One class of mitochondrial disorders that is genetic but not familial is caused by spontaneous mtDNA deletions or duplications. These include Kearns–Sayre syndrome and chronic progressive external ophthalmoplegia, which manifest in older individuals. The manifestation in early infancy is Pearson syndrome. This disorder manifests with anemia, ringed sideroblasts, and exocrine pancreatic dysfunction. This disease of the bone marrow can lead to death in infancy. However, patients able to recover or who benefit from aggressive therapy may demonstrate other signs of this systemic disorder in late infancy or childhood, such as poor growth, pancreas dysfunction, mitochondrial myopathy, lactic acidosis, and progressive neurologic damage, and develop Kearns–Sayre syndrome (DiMauro and Hirano, 1993).

Barth Syndrome

Barth syndrome is an X-linked disorder associated with cardiomyopathy, skeletal muscle disease, and neutropenia (Ferreira et al.,

1993). Skeletal muscle shows abnormal mitochondrial morphology and deficiencies of respiratory chain complexes III and IV. The *TAZ* gene encodes tafazzin, a cardiolipin acyltransferase, which leads to disruption of the inner mitochondrial membrane and disruption of ETC function. The accumulation of NADH and FADH₂ inhibit the TCA cycle, driving lactic acidosis, the development of muscle weakness, and cardiomyopathy. Urine organic acid analysis will show an increased urinary excretion of 3-methylglutaconic acid. Barth syndrome is also known as *3-methylglutaconic aciduria type II* but is genetically distinct from primary 3-methylglutaconic aciduria type I, caused by mutations in *AUH* involved in leucine metabolism, and other forms of 3-methylglutaconic aciduria (Gaspard and McMaster, 2015). Patients must be supported from birth to early infancy as acute neonatal presentations may have lactic acidosis, hypoglycemia, hyperammonemia, and liver dysfunction. Fetal loss and stillbirth have also been reported. Treatment includes standard support for heart failure and neutropenia as well as nutrition support and physical therapy (Ferreira et al., 1993).

Early Lethal Lactic Acidosis

In some patients with primary disturbances of mitochondrial ETC, massive lactic acidosis develops within 24 to 72 hours of birth. Commonly the condition is untreatable, because it is relentless and unresponsive to buffer therapy (Danhauser et al., 2015). Dialysis may be helpful but is not a cure and is not feasible in all patients. Often, affected infants have no obvious organ damage early in the course or evidence of malformations. In addition, acidemia per se can easily cause the coma or impaired cardiac contractility that may be encountered. Some infants have survived with aggressive therapy, and specific treatments can include thiamine, biotin, riboflavin, coenzyme Q10, or carnitine (Danhauser et al., 2015). Overall prognosis is likely poor, and the care of neonates with severe lactic acidosis is difficult as the prognosis is unclear. Decisions regarding management must be individualized, because the mitochondrial dysfunction and resultant pathophysiology can vary among infants, and expedited nuclear and mitochondrial DNA testing, to facilitate diagnosis and therefore guide prognosis, should be considered.

Lysosomal Storage, Peroxisomal, and Glycosylation Disorders and Smith–Lemli–Opitz Syndrome Presenting in the Neonate

JANET A. THOMAS, CHRISTINA LAM, AND GERARD T. BERRY

KEY POINTS

- Lysosomal storage diseases (LSDs) may present in the extended neonatal period. Findings may include nonimmune hydrops fetalis, brain disease and seizures, cherry-red spot, dysmorphic facial features, dysostosis multiplex, and/or hepatomegaly. An LSD may be diagnosed via an enzyme assay and/or DNA sequencing; newborn screening (NBS) for LSDs has generated ethical and moral concerns, as well as controversy.
- Many of the LSDs may be treated with enzyme replacement therapy (ERT).
- The phenotypic spectrum of glycosylation disorders is broad and ranges from mild to severe and from single organ system to multisystem disease; glycosylation defects should be considered in any unexplained clinical condition but especially in multiorgan disease with neurologic involvement.
- Most glycosylation disorders have been diagnosed molecularly since the advent of clinical next-generation sequencing testing.
- Treatment of glycosylation defects is mainly supportive, with the exceptions of more targeted therapies being available for MPI-CDG, SLC35C1-CDG, PIGM-CDG, and PGM1-CDG.
- Peroxisomal disorders are a broad and heterogeneous group of inherited diseases that result from the absence or dysfunction of one or more peroxisomal enzymes.
- Features are typically evident in the newborn and are most often multisystem features, including craniofacial dysmorphism, neurologic dysfunction, including hearing and vision dysfunction, hepatodigestive dysfunction, renal cysts, and skeletal abnormalities.
- Diagnosis of peroxisomal disorders is best made by next-generation sequencing techniques following abnormal biochemical screening test findings.
- Treatment of individuals with peroxisomal disorders is largely symptomatic and supportive.
- Smith–Lemli–Opitz syndrome (SLOS) is a multisystemic, developmental, and dysmorphic disorder with a wide clinical spectrum caused by a defect in cholesterol biosynthesis.
- Diagnosis of SLOS is based on elevated 7-dehydrocholesterol and 8-dehydrocholesterol levels in the blood.
- Treatment of SLOS mainly involves supportive management and exogenous cholesterol supplementation.

CONTROVERSY BOX

Newborn Screening for Lysosomal Storage Diseases

Certain physicians and ethicists consider it premature to mandate state newborn screening for lysosomal storage diseases such as Krabbe disease, as the natural history of each disease with its different genotypes and phenotypes is not known and improvement in outcome with early intervention is not proven. In other disorders the presentation is later in life and not in the newborn period (e.g., Fabry disease) and thus is not consistent with the original paradigm of newborn screening. In addition, many states do not have the human resources or financial resources to ensure an accurate diagnosis and proper long-term medical care. An opposing view is that it is our moral duty to treat these patients and alleviate suffering as soon and as best as possible and to reduce or eliminate the diagnostic odyssey that many individuals suffer before diagnosis.

Lysosomal storage disorders (LSDs), peroxisomal disorders, congenital disorders of glycosylation (CDGs), and Smith–Lemli–Opitz syndrome (SLOS) are single-gene disorders, most of which demonstrate autosomal recessive inheritance. The combined incidence of LSDs has been reported to be 1 in 1500 to 1 in 8000 live births in the United States, Europe, and Australia (Stone and Sidransky, 1999; Winchester et al., 2000; Wenger et al., 2003; Fletcher, 2006; Meikle et al., 2006; Staretz-Chacham et al., 2009). The incidence of peroxisomal disorders is estimated to be more than 1 in 20,000. The most current estimate for SLOS

Case Study 1

C.J. was a 2200 g girl born to a 24-year-old mother (third pregnancy, second viable child) after a 32-week gestation by cesarean delivery performed for fetal distress. The pregnancy was complicated by the finding on ultrasonography of fetal hydrops and ascites and possible hepatosplenomegaly at 24 weeks' gestation. Fetal blood sampling showed a hematocrit of 31% and elevations of γ -glutamyltransferase and aspartate transaminase values. The results of viral studies were negative and chromosomes were normal. At delivery, the newborn was limp and blue, with a heart rate of 60 beats per minute. Physical examination and chest radiograph showed marked abdominal distention, hepatosplenomegaly, multiple petechiae and bruises, a bell-shaped thorax, generalized hypotonia, talipes equinovarus, contractures at the knees, a large heart, and hazy lung fields with low volumes. Disseminated intravascular coagulopathy and evidence of liver disease developed rapidly, with elevated aspartate transaminase and γ -glutamyltransferase levels and increasing hyperbilirubinemia. The patient received mechanical ventilatory support and antibiotics for possible sepsis.

The results of evaluations for bacterial and viral agents were negative. Metabolic studies, including studies of ammonia, lactate, very long chain fatty acids, and urine amino and organic acids, yielded unremarkable measurements. The white blood cells were noted to have marked toxic granularity consistent with overwhelming bacterial sepsis or metabolic storage disease.

The patient experienced continued cardiorespiratory deterioration, had bilateral pneumothoraces and pneumopericardium, and died on the third day of life. Consent for autopsy was obtained from the family. A standard autopsy was performed and showed the presence of large, membrane-bound vacuoles within hepatocytes, endothelial cells, pericytes, and bone marrow stromal cells, which are typical of a metabolic storage disorder. Similar cells were also found within the placenta. There was no evidence of an infectious cause. Unfortunately, because a lysosomal storage disorder was not considered as a possible cause at the time of death, no frozen tissue or cultured fibroblasts were available to pursue the diagnosis. As a result of efforts by a research laboratory and the recurrence of disease in the couple's subsequent pregnancy, a diagnosis of β -glucuronidase deficiency, or mucopolysaccharidosis type VII, was confirmed.

is 1 in 20,000, and a similar frequency of 1 in 20,000 is estimated for the CDGs.

These four categories of metabolic diseases involve molecules important in cell membranes and share overlapping clinical presentations. The clinical presentations are heterogeneous, with a broad range of age at presentation and severity of symptoms. All are chronic and progressive. The age of onset ranges from prenatal to adulthood, and severity can range from severe disability and early death to nearly normal lifestyle and life span. For each condition, interfamilial variability is greater than intrafamilial variability. The genetic and clinical characteristics of conditions in these categories that can manifest themselves in the neonatal period (except Pompe disease, which is addressed in Chapter 22) are summarized in [Tables 23.1–23.2](#).

Important presentations that should lead the neonatologist to consider these disorders in the differential diagnosis are as follows:

1. In utero infection—hepatosplenomegaly and hepatopathy, possibly with extramedullary hematopoiesis
2. Nonimmune hydrops fetalis, ichthyotic or collodion skin, or both
3. Neurologic only—early and often difficult to control seizures, hypertonia, or hypotonia, with or without altered head size and with or without eye findings

Case Study 2

M.E. was born by normal spontaneous vaginal delivery, at term according to dates based on early ultrasonography, with a weight of 2200 g, a length of 45 cm, and a head circumference of 31.5 cm. On the basis of physical examination, the gestational age was assessed as 36 weeks. A heart murmur was noted, and investigation showed the presence of a small ventricular septal defect with no hemodynamic significance. Submucous cleft palate was noted. Examination for dysmorphic features showed simple, posteriorly rotated ears, mild epicanthic folds, micrognathia, and unilateral simian crease. Tone was moderately decreased. Irritability and severe feeding problems were noted, and gavage feeding was required; growth was poor despite adequate intake of calories. The results of a karyotype analysis were normal, and the results of studies for velocardiofacial syndrome were negative. Vomiting developed, and further evaluation showed no acidosis, hypoglycemia, or hyperammonemia. Liver-associated values and cholesterol level were normal, as were results of studies of amino acids, organic acids, and acylcarnitine profile. Vomiting became severe and did not respond to elemental formula, and pyloric stenosis was detected. Feeding problems persisted after successful surgical correction. Delivery of more than 140 kcal/kg by gavage was poorly tolerated but resulted in weight gain; however, length and head growth remained poor.

Smith–Lemli–Opitz syndrome was suggested despite the normal cholesterol value obtained on analysis in the hospital laboratory. Studies performed in a specialized laboratory showed the 7-dehydrocholesterol and 8-dehydrocholesterol values to be elevated and the cholesterol value to be decreased. Cholesterol supplementation led to some improvement in behavior and feeding. A decrease to 110 kcal/kg per day was tolerated without worsening of growth, and weight for height gradually returned to normal. A review of records confirmed that the pregnancy had been accurately dated by ultrasonography at 10 weeks' gestation, confirming that M.E. was small for gestational age and microcephalic at birth, with subsequent growth typical of Smith–Lemli–Opitz syndrome. The incorrect assessment of gestational age as 36 weeks on examination was found to result from a failure to appreciate the effect of hypotonia on the findings for gestational age. The family was counseled about autosomal recessive inheritance, including the availability of prenatal diagnosis.

Case Study 3

H.K. was born at term to healthy parents by cesarean delivery performed for breech presentation after an otherwise uncomplicated pregnancy. Hypotonia and dysmorphic features were noted in the delivery room, including inner epicanthic folds, flat occiput, large fontanelles, shallow orbital ridges, low nasal bridge, micrognathia, redundant skin folds at the neck, and unilateral simian crease. Brushfield spots were present. Investigation of a heart murmur revealed patent ductus arteriosus and a small atrial septal defect. There was mild hepatomegaly but normal liver function, no acidosis, and no hypoglycemia. Suck was poor, and gavage feeding was required.

The results of a karyotype analysis were normal, and there was no evidence of trisomy 21 in blood in 50 interphase cells examined. The option of skin biopsy to search further for evidence of mosaicism for trisomy 21 was considered. Thyroid function values were normal. Urine amino and organic acid values were normal, as was the acylcarnitine profile. Plasma very long chain fatty acid analysis showed elevation consistent with a diagnosis of Zellweger syndrome, along with a typical increase in pipecolic acid value and impaired capacity for fibroblast synthesis of plasmalogens. The baby died at 3 months of age, and autopsy showed polymicrogyria and small hepatic and renal cysts. The family was counseled about autosomal recessive inheritance, including the availability of prenatal diagnosis.

Case Study 4

M.J. had hypotonia at birth after an uncomplicated pregnancy. Minor dysmorphic features were noted, including high nasal bridge, large ears, and inverted nipples. Feeding difficulties were significant, and growth was poor. The findings on head ultrasonography were unremarkable, as were those of head magnetic resonance imaging, although the radiologist questioned whether the cerebellum might be slightly small. The results of a karyotype analysis were normal. There was no acidosis or hypoglycemia, and liver enzyme values were normal; the results of amino and organic acid analyses and the acylcarnitine profile were normal.

The baby was discharged on a diet providing 130 kcal/kg per day. On follow-up, growth remained poor, and development was severely delayed. At 6 months of age, she was admitted to the hospital for an episode of dehydration and irritability after gastroenteritis. Mild acidosis, borderline elevations of lactate and ammonia levels, and significant elevation of liver enzyme levels were noted over the course of the hospital stay. The liver enzyme levels remained elevated after discharge. Cardiac ultrasonography showed a small pericardial effusion, which resolved. Amino and organic acid values were normal, as was the acylcarnitine profile. Urine oligosaccharide levels showed an unusual pattern, and urine mucopolysaccharide values were normal.

At 2 years of age, developmental delay remained marked, and hypotonia persisted with reflexes absent. The creatinine phosphokinase level was normal, but liver function values remained abnormal. Because mitochondrial disease was suspected, the patient was scheduled for liver biopsy, but clotting values were abnormal. A congenital disorder of glycosylation was suspected, and a transferrin assay confirmed the diagnosis. A review of neonatal records revealed a comment from a neurology consultant about the unusual distribution of fat on the buttocks and thighs of M.J. as a neonate. The family was counseled about autosomal recessive inheritance, including availability of prenatal diagnosis.

4. Coarse facial features with bone changes, dysostosis multiplex, or osteoporosis
 5. Dysmorphic facial features with or without major malformations
 6. Rarely, known family history or positive prenatal diagnosis
- Only for the last three presentations are these conditions likely to be considered early in the differential diagnosis. Most babies with these conditions are born to healthy, nonconsanguineous couples with normal family histories, and these disorders are usually considered late, if at all, as in Case Study 1.

Lysosomal Storage Disorders

Lysosomes are single membrane-bound intracellular organelles that contain enzymes called *hydrolases*. These lysosomal enzymes are responsible for splitting large molecules into simple, low-molecular-weight compounds, which can be recycled. The materials digested by lysosomes and derived from endocytosis and phagocytosis are separated from other intracellular materials by the process of autophagy, which is the main mechanism whereby endogenous molecules are delivered to lysosomes. The common element of all compounds digested by lysosomal enzymes is that they contain a carbohydrate portion attached to a protein or lipid. These glycoconjugates include glycoproteins, glycosaminoglycans (GAGs), and glycolipids.

Glycolipids are large molecules with carbohydrates attached to a lipid moiety. Sphingolipids, globosides, gangliosides, cerebroside, and lipid sulfates all are glycolipids. The different classes of glycolipids are distinguished from one another primarily by different polar groups at C-1. Sphingolipids are complex membrane lipids

composed of one molecule of each of the amino alcohol sphingosine, a long-chain fatty acid, and various polar head groups attached by a β -glycosidic linkage. Sphingolipids occur in the blood and nearly all tissues of the body, the highest concentration being found in white matter of the central nervous system (CNS). In addition, various sphingolipids are components of the plasma membrane of practically all cells. The core structure of natural sphingolipids is ceramide, a long-chain fatty acid amide derivative of sphingosine. Free ceramide, an intermediate in the biosynthesis and catabolism of glycosphingolipids and sphingomyelin, composes 16%–20% of normal lipid content of stratum corneum of the skin. Sphingomyelin, a ceramide phosphocholine, is one of the principal structural lipids of membranes of nervous tissue.

Cerebrosides are a group of ceramide monohexosides with a single sugar, either glucose or galactose, and an additional sulfate group on galactose. The two most common cerebroside are galactocerebroside and glucocerebroside. The largest concentration of galactocerebroside is found in the brain. Glucocerebroside is an intermediate in the synthesis and degradation of more complex glycosphingolipids. Gangliosides, the most complex class of glycolipids, contain several sugar units and one or more sialic acid residues. Gangliosides are normal components of cell membranes and are found in high concentrations in ganglion cells of the CNS, particularly in nerve endings and dendrites. GM1 is the major ganglioside in the brain of vertebrates.

Gangliosides function as receptors for toxic agents, hormones, and certain viruses, are involved in cell differentiation, and can also have a role in cell–cell interaction by providing specific recognition determinants on the surface of cells. Ceramide oligosaccharides (i.e., globosides) are a family of cerebroside that contain two or more sugar residues, usually galactose, glucose, or *N*-acetylgalactosamine. GAGs and oligosaccharides are essential constituents of connective tissue, parenchymal organs, cartilage, and the nervous system.

GAGs, also called *mucopolysaccharides*, are complex heterosaccharides consisting of long sugar chains rich in sulfate groups. The polymeric chains are bound to specific proteins (core proteins). Glycoproteins contain oligosaccharide chains (long sugar molecules) attached covalently to a peptide core. Glycosylation occurs in the endoplasmic reticulum and Golgi apparatus. Most glycoproteins are secreted from cells and include transport proteins, glycoprotein hormones, complement factors, enzymes, and enzyme inhibitors. There is extensive diversity in the composition and structure of oligosaccharides.

The degradation of glycolipids, GAGs, and glycoproteins occurs especially within lysosomes of phagocytic cells, related to histiocytes and macrophages, in any tissue or organ. A series of hydrolytic enzymes cleaves specific bonds, resulting in sequential, stepwise removal of constituents such as sugars and sulfate and degrading complex glycoconjugates to the level of their basic building blocks. LSDs most commonly result when an inherited defect causes significantly decreased activity in one of these hydrolases. Other causes are failure of transport of an enzyme, substrate, or product. Whatever the specific cause, incompletely metabolized molecules accumulate, especially within the tissue responsible for catabolism of the glycoconjugate. Additional excess storage material may be excreted in urine. The mechanisms of cellular dysfunction and damage in most LSDs remain unknown. Various hypotheses have been offered, such as a pivotal disturbance in the normal process of autophagy (Kiselyov et al., 2007; Ballabio and Gieselmann, 2009). In this pathophysiologic construct, endoplasmic reticulum membrane engulfment of cellular components, such as mitochondrial derivatives targeted for destruction, is perturbed. As a consequence,

TABLE
23.1

Lysosomal Storage Disorders in the Newborn Period: Genetic and Clinical Characteristics of Neonatal Presentation

| Disorder | Onset | Facies | Neurologic Findings | Distinctive Features | Eye Findings |
|---------------------------------------|-----------------------------|---------------------|--|--|---|
| Niemann–Pick A disease | Early infancy | Frontal bossing | Difficulty feeding, apathy, deafness, blindness, hypotonia | Brownish-yellow skin, xanthomas | Cherry-red spot (50%) |
| Niemann–Pick C disease | Birth–3 months | Normal | Developmental delay, vertical gaze paralysis, hypotonia, later spasticity | – | – |
| Gaucher disease type 2 | In utero–6 months | Normal | Poor suck and swallow, weak cry, squint, trismus, strabismus, opsochonus, hypertonic, later flaccidity | Congenital ichthyosis, collodion skin | – |
| Krabbe disease | 3–6 months | Normal | Irritability, tonic spasms with light or noise stimulation, seizures, hypertonia, later flaccidity | Increased CSF protein level | Optic atrophy |
| GM1 gangliosidosis | Birth | Coarse | Poor suck, weak cry, lethargy, exaggerated startle, blindness, hypotonia, later spasticity | Gingival hypertrophy, edema, rashes | Cherry-red spot (50%) |
| Farber disease type I | 2 weeks–4 months | Normal | Progressive psychomotor impairment, seizures, decreased reflexes, hypotonia | Joint swelling with nodules, hoarseness, lung disease, contractures, fever, granulomas, dysphagia, vomiting, increased CSF protein level | Grayish opacification surrounding retina in some patients, subtle cherry-red spot |
| Farber disease types II and III | Birth–9 months (≤20 months) | Normal | | Joint swelling with nodules, hoarseness | Normal macula, corneal opacities |
| Farber disease type IV (neonatal) | Birth | Normal | Nodules not consistent findings | Corneal opacities (1/3) | – |
| Congenital sialidosis | In utero–birth | Coarse, edema | Mental retardation, hypotonia | Neonatal ascites, inguinal hernias, renal disease | Corneal clouding |
| Galactosialidosis | In utero–birth | Coarse | Mental retardation, occasional deafness, hypotonia | Ascites, edema, inguinal hernias, renal disease, telangiectasias | Cherry-red spot, corneal clouding |
| Wolman disease | First weeks of life | Normal | Mental deterioration | Vomiting, diarrhea, steatorrhea, abdominal distention, failure to thrive, anemia, adrenal calcifications | – |
| Infantile sialic acid storage disease | In utero–birth | Coarse, dysmorphic | Mental retardation, hypotonia | Ascites, anemia, diarrhea, failure to thrive | – |
| I-cell disease | In utero–birth | Coarse | Mental retardation, deafness | Gingival hyperplasia, restricted joint mobility, hernias | Corneal clouding |
| Mucopolipidosis type IV | Birth–3 months | Normal | Mental retardation, hypotonia | – | Severe corneal clouding, retinal degeneration, blindness |
| Mucopolysaccharidosis type VII | In utero–childhood | Variable coarseness | Mild to severe mental retardation | Hernias | Variable corneal clouding |

TABLE 23.2**Common Clinical Features of Congenital Disorders of Glycosylation by Pathway**

| Pathway | Example Disorders | Neurologic | Ophthalmologic | Cardiologic | Gastroenterologic |
|------------------------|--|--|--|---|--|
| N-linked glycosylation | PMM2-CDG, MPI-CDG, ALGx-CDG, MOGS-CDG | ID (except MPI), DD, seizures (50%), hypotonia, ataxia, dysmetria, dysarthria, peripheral neuropathy, cerebral and cerebellar atrophy, myasthenic syndrome | Strabismus, nystagmus, optic hypoplasia, retinal pigmentary changes, alacrima | Pericardial effusion, cardiomyopathy, fetal hydrops | Protein-losing enteropathy, diarrhea, failure to thrive, gastroesophageal reflux, hepatopathy with elevated AST and ALT levels, edema and hypoalbuminemia, low cholesterol level |
| O-linked glycosylation | GALNT3-CDG, B3GLCT-CDG, POMK-CDG, EXT1-CDG, CHST-CDG | ID (not universal), DD, congenital and later-onset muscular dystrophy, hypotonia, polymicrogyria, lissencephaly | Peters plus syndrome, other structural eye abnormalities, glaucoma, isolated macular corneal dystrophy, corneal opacity, cataracts | | Failure to thrive |
| Mixed glycosylation | COGx-CDG, TMEMx-CDG | Seizures, ID (not universal), DD, microcephaly, hypotonia, cortical and cerebellar atrophy | All findings seen in N-linked pathway possible | Cardiomyopathy, congenital structural heart defects | All findings seen in N-linked pathway possible, isolated polycystic liver disease, high cholesterol level, cholestatic liver disease, prenatal growth retardation |
| GPI anchor disorder | PIGx-CDG, PGAPx-CDG | Seizures, ID, DD, macrocephaly, hypotonia | | Congenital heart defects, cardiomyopathy | |
| Lipid glycosylation | ST3GAL5-CDG (Amish infantile epilepsy syndrome) | Seizures, ID, DD, hypotonia, diffuse brain atrophy, irritability, microcephaly | Optic atrophy, cortical visual impairment | | Failure to thrive |

ALT, Alanine transaminase; AST, aspartate transaminase; DD, developmental disability; GPI, glycosylphosphatidylinositol; ID, intellectual disability; IGF1, insulin-like growth factor 1.

deleterious pathways become activated, leading to unwanted ubiquitination of targeted molecules and apoptosis.

LSDs are classified according to the stored compound. The clinical phenotype depends partially on the type and amount of storage substance. There are more than 50 different LSDs, and a significant fraction, approximately 20 LSDs, may have manifestations in the newborn (Staretz-Chacham et al., 2009). The disorders selected for discussion in this chapter are all known to manifest themselves in the neonatal period.

Clinical Presentations

Table 23.1 summarizes the clinical characteristics of the neonatal presentations of LSDs.

Niemann–Pick A Disease (Acute, Sphingomyelinase Deficient)

Etiology

Niemann–Pick A disease is caused by a deficiency of sphingomyelinase. Sphingomyelinase catalyzes the breakdown of sphingomyelin

to ceramide and phosphocholine, and its deficiency results in sphingomyelin storage within lysosomes. Cholesterol is also stored, suggesting that its metabolism is tied to that of sphingomyelin. Sphingomyelin normally composes 5%–20% of phospholipids in the liver, spleen, and brain, but in these disorders it can compose up to 70% of phospholipids. Individuals with Niemann–Pick A disease usually have enzyme activity less than 5% of normal.

Clinical Features

Clinical features of this disorder may appear in utero or up to 1 year of age. Affected infants usually have massive hepatosplenomegaly (hepatomegaly greater than splenomegaly), constipation, feeding difficulties, and vomiting, with consequent failure to thrive. Patients eventually appear strikingly emaciated with a protuberant abdomen and thin extremities. Neurologic disease is evident by 6 months of age, with hypotonia, decrease or absence of deep tendon reflexes, and weakness. Loss of motor skills, spasticity, rigidity, and loss of vision and hearing occur later. Seizures are rare. A retinal cherry-red spot is present in about half of cases, and the electroretinographic findings are abnormal. Respiratory infections are

KEY FEATURES BY SYSTEM

| Hematologic | Renal | Endocrine | Dermatologic | Musculoskeletal/Other | Diagnostic Screen |
|---|---|---|--|--|---|
| Factors II, V, VII, VIII, IX, X, and XI, antithrombin III, protein C, protein S deficiency, increased bleeding tendency, thrombotic events, hypogammopathy, coagulopathy and thrombosis | Hyperechoic kidneys, microcystic changes, proteinuria | Abnormal thyroid function test findings, short stature, IGF1 deficiency, hypogonadotropic hypogonadism, hyperinsulinemic hypoglycemia | Lipodystrophy, hypohidrosis | Osteopenia, kyphoscoliosis, dysmorphic features, skeletal dysplasia | Transferrin profiling, urine oligosaccharide analysis |
| | | Tumoral calcinosis with phosphatemia | Loose skin, Dowling–Degos disease | Skeletal dysplasia, short stature, Ehlers–Danlos syndrome, hypermobility, exostoses, elevated creatine kinase, dysmorphic facies | |
| Isolated leukocyte adhesion deficiency, isolated congenital dyserythropoietic anemia type II, immunodeficiency | Obstructive uropathy, micropenis, hypospadias | | Ichthyosis, cutis laxa, hypohidrosis | Skeletal dysplasia, dysmorphic features, elevated creatine kinase level | Transferrin profiling with apolipoprotein CIII profiling |
| | | Accelerated linear growth, advanced bone age, with or without hyperphosphatasia | | Dysmorphic features, multiple congenital anomalies | Flow cytometry studies using cell surface markers such as FLAER and CD59 on granulocytes, lymphocytes, etc. |
| | | | Dyspigmentation, “salt and pepper” pattern on skin macules | | |

common. The skin may have an ochre or brownish-yellow color, and xanthomas have been observed. Radiographic findings consist of widening of medullary cavities, cortical thinning of long bones, and osteoporosis. In the brain and spinal cord, neuronal storage is widespread, leading to cytoplasmic swelling together with atrophy of cerebellum. Bone marrow and tissue biopsy samples may show foam cells or sea-blue histiocytes, which represent lipid-laden cells of the monocyte–macrophage system. Similarly, vacuolated lymphocytes or monocytes may be present in peripheral blood. Tissue cholesterol levels may be threefold to tenfold that of normal, and patients may have a microcytic anemia and thrombocytopenia. Death occurs by 2–3 years of age.

Niemann–Pick C Disease

Etiology

Niemann–Pick C disease is caused by an error in the intracellular transport of exogenous low-density lipoprotein (LDL)-derived cholesterol, which leads to impaired esterification of cholesterol and trapping of unesterified cholesterol in lysosomes. The incidence may be higher than 1 in 150,000 births (Wraith et al., 2009).

Cell lines from patients can be divided into two complementation groups, Niemann–Pick C (NPC)1 and NPC2, corresponding to different genes (Millat et al., 2001). In each group the primary defect is abnormal cholesterol esterification, but the enzyme responsible for cholesterol esterification—acetyl coenzyme A (CoA) acetyltransferase (ACAT)—is not deficient. The storage of sphingomyelin is secondary. It has been suggested that the defect is in transport of cholesterol out of the lysosome, making cholesterol unavailable to ACAT (Natowicz et al., 1995). Sphingomyelinase activity appears normal or elevated in most tissues but is partially deficient (60%–70%) in fibroblasts from most patients with this disorder. Storage of sphingomyelin in tissues is much less than in Niemann–Pick A or Niemann–Pick B disease and is accompanied by additional storage of unesterified cholesterol, phospholipids, and glycolipids in the liver and spleen. Only glycolipids levels are increased in the brain.

Clinical Features

The age of onset, clinical features, and natural history of Niemann–Pick C disease are highly variable. Onset can occur from birth to

18 years of age. Fifty percent of children with onset in the neonatal period have conjugated hyperbilirubinemia, which usually resolves spontaneously but is followed by neurologic symptoms later in childhood. In the severe infantile form, hepatosplenomegaly is common, accompanied by hypotonia and delayed motor development. Further mental regression is usually evident by the age of 1–1.5 years, in association with behavior problems, vertical supranuclear ophthalmoplegia, progressive ataxia, dystonia, spasticity, dementia, drooling, dysphagia, and dysarthria. Seizures are rare. Foam cells and sea-blue histiocytes may be found in many tissues. Neuronal storage with cytoplasmic ballooning, inclusions, meganeurites, and axonal spheroids are also seen. Death may occur in infancy or as late as the third decade of life. Niemann–Pick C disease can also manifest itself as fatal neonatal liver disease, often misdiagnosed as fetal hepatitis. Patients with mutations in the *NPC2* gene (also known as *HE1*) may have remarkable features consisting of pronounced pulmonary involvement leading to early death caused by respiratory failure (Millat et al., 2001).

Gaucher Disease Type 2 (Acute Neuropathic)

Etiology

Three types of Gaucher disease have been defined. Type 1, the nonneuropathic form, is the most common and is distinguished from types 2 and 3 by the lack of CNS involvement. Type 1 disease most commonly manifests itself in early childhood but may do so in adulthood. Type 2 disease, the acute neuropathic form, is characterized by infantile onset of severe CNS involvement. Type 3 disease, the subacute neuropathic form, is also late in onset, with slow neurologic progression. Almost all types of Gaucher disease are caused by a deficiency of lysosomal glucocerebrosidase and result in storage of glucocerebroside in visceral organs; the brain is affected in types 2 and 3. Although there is significant variability in clinical presentation among individuals with the same mutations, there is a clear correlation between certain mutations and clinical symptoms involving the CNS (Beutler and Grabowski, 2001). Glucocerebrosidase splits glucose from cerebroside, yielding ceramide and glucose. A few patients with Gaucher disease type 2 have a deficiency of saposin C, a cohydrolase required by glucocerebrosidase.

Clinical Features

Typically, the age of onset of Gaucher disease type 2 is approximately 3 months, consisting of hepatosplenomegaly (splenomegaly predominates) with subsequent neurologic deterioration. Hydrops fetalis, congenital ichthyosis, and collodion skin, however, are well-described presentations (Lipson et al., 1991; Sidransky et al., 1992; Sherer et al., 1993; Fujimoto et al., 1995; Ince et al., 1995; Liu et al., 1988). In a review of 18 cases of Gaucher disease manifesting itself in the newborn period, Sidransky et al. (1992) found that eight patients had associated dermatologic findings and six patients had hydrops. The cause of the association of such findings in Gaucher disease is unclear, although the enzyme deficiency appears to be directly responsible (Sidransky et al., 1992). Ceramides have been shown to be major components of intracellular bilayers in epidermal stratum corneum, and they have an important role in skin homeostasis (Fujimoto et al., 1995). Therefore Gaucher disease should be considered in the differential diagnosis for infants with hydrops fetalis and congenital ichthyosis. For the subset of patients in the prenatal period or at birth, death frequently occurs within hours to days or at least within 2–3 months.

Krabbe Disease (Globoid Cell Leukodystrophy)

Etiology

The synonym for Krabbe disease, globoid cell leukodystrophy, is derived from the finding of large numbers of multinuclear macrophages in cerebral white matter that contain undigested galactocerebroside. Disease is caused by a deficiency of lysosomal galactocerebroside β -galactosidase, which normally degrades galactocerebroside to ceramide and galactose. Deficiency of the enzyme results in storage of galactocerebroside. Galactocerebroside is present almost exclusively in myelin sheaths. Accumulation of the toxic metabolite psychosine, also a substrate for the enzyme, has been postulated to lead to early destruction of oligodendroglia. Impaired catabolism of galactosylceramide is also important in the pathogenesis of the disease.

Clinical Features

The age of onset ranges from the first weeks of life to adulthood. The typical age of onset of infantile Krabbe disease is between 3 and 6 months, but there are cases of early onset in which neurologic symptoms are evident within weeks after birth. Symptoms and signs are confined to the nervous system; no visceral involvement is present. The clinical course has been divided into three stages. In stage I, patients who appeared relatively normal after birth exhibit hyperirritability, vomiting, episodic fevers, hyperesthesia, tonic spasms with light or noise stimulation, stiffness, and seizures. Peripheral neuropathy is present, but reflexes are increased. Stage II is marked by CNS deterioration and hypertonia that progresses to hypotonia and flaccidity. Deep tendon reflexes are eventually lost. Patients with stage III disease are decerebrate, deaf, and blind with hyperpyrexia, hypersalivation, and frequent seizures. Routine laboratory findings are unremarkable except for an elevation of the level of cerebrospinal fluid protein. Cerebral atrophy and demyelination become evident in the CNS, and segmental demyelination, axonal degeneration, fibrosis, and macrophage infiltration are common in the peripheral nervous system. The segmental demyelination of peripheral nerves is demonstrated by the finding of decreased motor nerve conduction. The white matter is severely depleted of all lipids, especially glycolipids, and nerve and brain biopsies show globoid cells. Death from hyperpyrexia, respiratory complications, or aspiration occurs at a median age of 13 months.

GM1 Gangliosidosis

Etiology

Infantile GM1 gangliosidosis is caused by a deficiency in lysosomal β -galactosidase. The enzyme cleaves the terminal galactose in a β linkage from oligosaccharides, keratan sulfate, and GM1 ganglioside. Deficiency of the enzyme results in storage of GM1 ganglioside and oligosaccharides. Clinical severity correlates with the extent of substrate storage and residual enzyme activity. The same enzyme is deficient in Morquio disease type B.

Clinical Features

The age of onset ranges from prenatal to adult. Infantile or type 1 GM1 gangliosidosis may be evident at birth as coarse and thick skin, hirsutism on the forehead and neck, and coarse facial features consisting of a puffy face, frontal bossing, depressed nasal bridge, maxillary hyperplasia, large and low-set ears, wide upper lip, moderate macroglossia, and gingival hypertrophy. These dysmorphic features, however, are not always obvious in the neonate. A retinal cherry-red spot is seen in 50% of patients, and corneal clouding is often observed. Shortly after birth, or by 3–6 months of age,

failure to thrive and hepatosplenomegaly become evident, as does neurologic involvement with poor development, hyperreflexia, hypotonia, and seizures. Cranial imaging shows diffuse atrophy of the brain, enlargement of the ventricular system, and evidence of myelin loss in white matter.

The neurologic deterioration is progressive, resulting in generalized rigidity and spasticity and sensorimotor and psychointellectual dysfunction. By 6 months of age, skeletal features are present, including kyphoscoliosis and stiff joints with generalized contractures, and striking bone changes are seen—vertebral beaking in the thoracolumbar region, broadening of shafts of the long bones with distal and proximal tapering, and widening of the metacarpal shafts with proximal pinching of four lateral metacarpals. Tissue biopsy samples demonstrate neurons filled with membranous cytoplasmic bodies and various types of inclusions as well as foam cells in the bone marrow. Death generally occurs before 2 years of age. A severe neonatal-onset type of GM1 gangliosidosis with cardiomyopathy has also been described (Kohlschütter et al., 1982).

Farber Lipogranulomatosis

Etiology

Farber lipogranulomatosis results from a deficiency of lysosomal acid ceramidase. Ceramidase catalyzes the degradation of ceramide to its long-chain base, sphingosine, and a fatty acid. Clinical disease is a consequence of storage of ceramide in various organs and body fluids.

Clinical Features

Four types of Farber lipogranulomatosis can manifest themselves in the neonatal period. Type I, classic disease, is a unique disorder with onset from approximately 2 weeks to 4 months of age. Patients exhibit hoarseness progressing to aphonia, feeding and respiratory difficulties, poor weight gain, and intermittent fever caused by granuloma formation and swelling of the epiglottis and larynx. Palpable nodules appear over joints and pressure points, and joints become painful and swollen. Later, joint contractures and pulmonary disease appear. Liver and cardiac involvement can occur, and patients can have a subtle retinal cherry-red spot. Severe and progressive psychomotor impairment can occur, as can seizures, decreased deep tendon reflexes, hypotonia, and muscle atrophy. Affected patients die in early infancy, usually of pulmonary disease.

Type 2, or intermediate, Farber lipogranulomatosis manifests itself from birth to 9 months of age as joint and laryngeal involvement and nodules. Death occurs in early childhood. Type 3 disease (mild) manifests itself slightly later, from approximately 2 months to 20 months of age, with survival into the third decade. Clinically types 2 and 3 are both dominated by subcutaneous nodules, joint deformity, and laryngeal involvement. Liver and pulmonary involvement may be absent. Two-thirds of patients have a normal intelligence quotient. Type 4, or neonatal visceral, Farber lipogranulomatosis manifests itself at birth as hepatosplenomegaly caused by massive histiocyte infiltration of the liver and spleen, with infiltration also in the lungs, thymus, and lymphocytes. Subcutaneous nodules and laryngeal involvement may be subtle. Death occurs by 6 months of age.

In all types of Farber lipogranulomatosis, tissue biopsy samples show granulomatous infiltration, foam cells, and lysosomes with comma-shaped, curvilinear tubular structures called *Farber bodies*. Cerebrospinal fluid protein level may be elevated in patients with type 1 disease.

Sialidosis

Etiology

Sialidosis is caused by a deficiency of neuraminidase, which is responsible for the cleavage of terminal sialyl linkages of several oligosaccharides and glycopeptides. The defect results in multisystem lysosomal accumulation of sugars rich in sialic acid.

Clinical Features

Type I sialidosis is characterized by retinal cherry-red spots and generalized myoclonus with onset generally in the second decade of life. Type II is distinguished from type I by the early onset of a progressive, severe phenotype with somatic features. Type II is often subdivided into juvenile, infantile, and congenital forms. Congenital sialidosis begins in utero and manifests itself at birth as coarse features, facial edema, hepatosplenomegaly, ascites, hernias, and hypotonia and occasionally frank hydrops fetalis. Radiographs demonstrate dysostosis multiplex and epiphyseal stippling. Delayed mental development is quickly apparent. The patient may have recurrent infections. Severely dilated coronary arteries, excessive retinal vascular tortuosity, and an erythematous macular rash may also be features of this disease (Buchholz et al., 2001). Most patients are stillborn or die before 1 year of age. The age of onset for the infantile form of sialidosis ranges from birth to 12 months. The clinical features include coarse facial features, organomegaly, dysostosis multiplex, retinal cherry-red spot, and mental retardation. Death occurs by the second or third decade. In both types of sialidosis, vacuolated cells can be seen in almost all tissues, and bone marrow foam cells are present.

Galactosialidosis

Etiology

Galactosialidosis results from a deficiency of two lysosomal enzymes, neuraminidase and β -galactosidase. The primary defect in galactosialidosis is a defect in the protective protein cathepsin A, an intralysosomal protein that protects the two enzymes from premature proteolytic processing. The protective protein has catalytic and protective functions, and the two functions appear to be distinct. Deficiency of the enzymes results in the accumulation of sialyloligosaccharides in tissue lysosomes and in excreted body fluids.

Clinical Features

Galactosialidosis has been divided into three phenotypic subtypes on the basis of age at onset and severity of clinical manifestations. Most cases occur in adolescence and adulthood, but early infantile and late infantile presentations occur. Patients develop early infantile galactosialidosis between birth and 3 months of age, with ascites, edema, coarse facial features, inguinal hernias, proteinuria, hypotonia, and telangiectasias, and, occasionally, frank hydrops fetalis. Patients subsequently demonstrate organomegaly, including cardiomegaly progressing to cardiac failure, psychomotor delay, and skeletal changes, particularly in the spine. Ocular abnormalities can occur, including corneal clouding and retinal cherry-red spots. Death occurs at an average age of 8 months, usually from cardiac and renal failure. Galactosialidosis can be a cause of recurrent fetal loss or recurrent hydrops fetalis.

Late infantile galactosialidosis manifests itself in the first months of life as coarse facial features, hepatosplenomegaly, and skeletal changes consistent with dysostosis multiplex. Cherry-red spots and corneal clouding may also be present. Neurologic involvement may be absent or mild. Valvular heart disease is a common feature,

as is growth retardation, partially because of spinal involvement and often in association with muscular atrophy. Early death is not a feature of the late infantile form. Vacuolated cells in blood smears and foam cells in bone marrow are present in all forms of galactosialidosis.

Wolman Disease

Etiology

Wolman disease is caused by a deficiency of lysosomal acid lipase, which is an enzyme involved in cellular cholesterol homeostasis and responsible for hydrolysis of cholesterol esters and triglycerides. The result of enzyme deficiency is defective release of free cholesterol from lysosomes, which leads to upregulation of LDL receptors and 3-hydroxy-3-methylglutaryl-CoA reductase activity. De novo synthesis of cholesterol and activation of receptor-mediated endocytosis of LDL then occur, leading to further deposition of lipid in lysosomes. The result is the accumulation of cholesterol esters and triglycerides in most tissues of the body, including the liver, spleen, lymph nodes, heart, blood vessels, and brain. An extreme level of lipid storage occurs in cells of the small intestine, particularly in the mucosa. In addition, neurons of the myenteric plexus demonstrate a high level of storage, with evidence of neuronal cell death, which may account for the prominence of gastrointestinal (GI) symptoms (Wolman, 1995).

Clinical Features

Clinical presentation of Wolman disease is within weeks of birth, with evidence of malnutrition and malabsorption, including symptoms of vomiting, diarrhea, steatorrhea, failure to thrive, abdominal distention, and hepatosplenomegaly. Adrenal calcifications may be seen on radiographs, and adrenal insufficiency appears. The presence of adrenal calcifications in association with hepatosplenomegaly and GI symptoms is strongly suggestive of Wolman disease. Later, mental deterioration becomes apparent. Laboratory findings include anemia secondary to foam cell infiltration of the bone marrow and evidence of adrenal insufficiency. The serum cholesterol level is normal. Death usually occurs before 1 year of age.

Infantile Sialic Acid Storage Disease

Etiology

Infantile sialic acid storage disease is caused by a defective lysosomal sialic acid transporter that is responsible for efflux of sialic acid and other acidic monosaccharides from the lysosomal compartment. The defective transporter results in greater storage of free sialic acid and glucuronic acid within lysosomes and increased sialic acid excretion.

Clinical Features

Infantile sialic acid storage disease often manifests itself at birth as mildly coarse features, hepatosplenomegaly, ascites, hypopigmentation, and generalized hypotonia. Mild dysostosis multiplex may be seen on radiographs. Failure to thrive and severe mental and motor retardation soon appear. Cardiomegaly may be present. Corneas are clear, but albinoid fundi have been reported (Lemyre et al., 1999). Vacuolated cells are seen in a tissue biopsy sample, and electron microscopy demonstrates swollen lysosomes filled with finely granular material. CNS changes include myelin loss, axonal spheroids, gliosis, and neuronal storage. Death occurs in early childhood. Infantile sialic acid storage disease can also manifest itself as fetal ascites, nonimmune fetal hydrops, or infantile nephrotic syndrome (Lemyre et al., 1999).

I-Cell Disease (Mucopolidosis Type II)

Etiology

In normal cells, targeting of enzymes to lysosomes is mediated by receptors that bind a mannose 6-phosphate recognition marker on the enzyme. The recognition marker is synthesized in a two-step reaction in the Golgi complex. It is the enzyme that catalyzes the first step of this process, uridine diphosphate-*N*-acetylglucosamine:lysosomal enzyme *N*-acetylglucosaminyl-1-phosphotransferase, that is defective in I-cell disease. As a result, the enzymes lack the mannose 6-phosphate recognition signal, and the newly synthesized lysosomal enzymes are secreted into the extracellular matrix instead of being targeted to the lysosome. Consequently, multiple lysosomal enzymes are found in plasma at 10–20 times their normal concentrations. Affected cells, especially fibroblasts, show dense inclusions of storage material that probably consists of oligosaccharides, GAGs, and lipids; these are the inclusion bodies from which the disease name is derived. This disorder is found more frequently in Ashkenazi Jews, because of a putative founder effect.

Clinical Features

I-cell disease can manifest itself at birth as coarse features, corneal clouding, organomegaly, hypotonia, and gingival hyperplasia. Birthweight and length are often below normal. Kyphoscoliosis, lumbar gibbus, and restricted joint movement are often present, and there may be hip dislocation, fractures, hernias, or bilateral talipes equinovarus. Dysostosis multiplex may be seen on radiographs. Severe psychomotor retardation, evident by 6 months of age, and progressive failure to thrive occur. The facial features become progressively coarser, with a high forehead, puffy eyelids, epicanthal folds, flat nasal bridge, anteverted nares, and macroglossia. Linear growth slows during the first year of life and halts completely thereafter. The skeletal involvement is also progressive, with development of increasing joint immobility and claw-hand deformities. Respiratory infections, otitis media, and cardiac involvement are common complications. Death usually occurs in the first decade of life because of cardiorespiratory complications.

Mucopolidosis Type IV

Etiology

Although mucopolidosis type IV is associated with a partial deficiency of the lysosomal enzyme ganglioside sialidase, a deficiency of mucopolipin 1, a member of the transient receptor potential mucopolipin subfamily of channel proteins, is the cause of the disorder (Bargal et al., 2000; Sun et al., 2000). Mutations in the *MCOLN1* gene result in lysosomal storage of lipids such as gangliosides, plus water-soluble materials such as GAGs and glycoproteins in cells from almost all tissues.

Clinical Features

The age of onset for mucopolidosis type IV ranges from infancy to 5 years. Presenting features include corneal clouding (may be congenital), retinal degeneration, blindness, hypotonia, and mental retardation. Survival of affected patients into the fourth decade of life has been reported (Chitayat et al., 1991). Cytoplasmic inclusions are noted in many cells, including those in conjunctiva, liver, and spleen, as well as fibroblasts.

Mucopolysaccharidosis Type VII (Sly Disease)

Etiology

Sly disease is a member of a group of LSDs that are caused by a deficiency of enzymes catalyzing the stepwise degradation of GAGs. Skeletal and neurologic involvement are variable. There is a wide

spectrum of clinical severity among the mucopolysaccharidoses and even within a single enzyme deficiency. Most of these disorders manifest themselves in childhood, but type VII is included in this chapter because of its well-recognized neonatal and infantile presentations. Sly disease is caused by β -glucuronidase deficiency and results in lysosomal accumulation of GAGs, including dermatan sulfate, heparan sulfate, and chondroitin sulfate, causing cell, tissue, and organ dysfunction.

Clinical Features

Sly disease can manifest itself as a wide spectrum of severity. Patients with the early-onset or neonatal form may have coarse features, hepatosplenomegaly, moderate dysostosis multiplex, hernias, and nonprogressive mental retardation. Corneal clouding is variably present. Frequent episodes of pneumonia during the first year of life are common. Short stature becomes evident. Granulocytes have coarse metachromatic granules. A severe neonatal form associated with hydrops fetalis and early death has been recognized frequently. Milder forms of the disease with later onset are also known.

Diagnosis, Management, and Prognosis

Growing recognition of LSDs in the neonate has led to expansion of the spectrum of possible clinical presentations in the newborn period. Diagnostic tools and options for treatment also continue to advance. For example, newborn screening (NBS) for mucopolysaccharidoses has begun in several states, with the goal to offer treatment with enzyme infusion or hematopoietic stem cell transplantation (HSCT) for affected babies (Vogler et al., 1999; Hopkins et al., 2015). The state of New York has implemented NBS for Krabbe disease that uses dried blood spots. The test uses a tandem mass spectrometry–based enzyme analysis (Li et al., 2004a). This test has resulted in a fairly large number of positive newborn screens for Krabbe disease, most of which appear to be false positives, including enzyme perturbations that are not linked with clinical disease (Duffner et al., 2009). As a consequence, an expert advising panel, the Krabbe Consortium of New York State, has been generated to establish standardized clinical evaluation guidelines (Wasserstein et al., 2016). The goal is to help physicians determine which infant with a positive newborn screen may express disease and require treatment, such as HSCT in early infancy. The neonatologist is urged to work closely with appropriate experts to explore diagnostic and treatment protocols on an individual basis. Larger panels of multiplex testing for various other LSDs are in the testing stages (Li et al., 2004b), and some states in the United States are poised to begin implementing LSD NBS. Currently a federal advisory committee actively reviews and makes recommendations to the US Secretary of Health and Human Services about the introduction of new NBS tests in the United States, with the aim of vetting proposed tests for need, cost-effectiveness, and availability of effective and timely therapy. The Recommended Universal Screening Panel has added mucopolysaccharidosis type I to the list of diseases that ought to be screened in every state. Ross (2012) performed an ethical and policy analysis using the Wilson and Jungner criteria for public health screening and concluded that the data do not support the incorporation of screens for LSDs into NBS programs. Instead, they should entail institutional review board–approved research protocols that require parental consent.

Recognizing LSDs in the newborn period can be difficult, because they often mimic more common causes of illness in newborns, such as respiratory distress, nonimmune hydrops fetalis, liver disease,

and sepsis. The initial step in the diagnosis of these disorders is to consider them in the differential diagnosis of a sick or unusual-appearing newborn. At times the phenotype may suggest a specific diagnosis, such as respiratory distress and painful, swollen joints in Farber lipogranulomatosis or GI symptoms, hepatosplenomegaly, and adrenal calcifications in Wolman disease. Subtle dysmorphic features, coarsening of features, and radiographic evidence of dysostosis multiplex are also strong indications that LSDs should be considered. Routine laboratory findings are often normal or nonspecific. Affected infants do not have episodes of acute metabolic decompensation. Anemia and thrombocytopenia may be seen because of bone marrow involvement. Vacuolated cells may be found in peripheral blood, but the absence of this finding does not exclude LSD. Elevated cerebrospinal fluid protein level is seen in Krabbe disease and Farber lipogranulomatosis type I.

Nonimmune hydrops fetalis deserves special mention. The physician must consider LSDs as the cause of nonimmune hydrops fetalis or unexplained ascites in the affected newborn. The following LSDs are potential causes: sialidosis type II, mucopolysaccharidosis types VII and IV, infantile sialic acid storage disease, Salla disease, galactosialidosis, Gaucher disease type 2, GM1 gangliosidosis, I-cell disease, Niemann–Pick disease types A and C, Wolman disease, and Farber disease (Staretz-Chacham et al., 2009). The mechanisms of edema are unclear. Furthermore, not all of the 13 LSDs routinely appear in the neonatal period.

Directed analysis of urine is helpful for conditions in which characteristic metabolites are excreted in urine. One- or two-dimensional electrophoresis or thin-layer chromatography can detect excess excretion of urine GAGs, oligosaccharides, or free sialic acid, but all urinary tests for the diagnosis of LSDs can have false-negative results. Examination of bone marrow or other tissues may demonstrate storage macrophages in Gaucher disease and in Niemann–Pick disease types A and C. Small skin or conjunctival biopsy specimens may demonstrate storage within lysosomes in most of these disorders.

Definitive diagnosis for all LSDs, except for Niemann–Pick C disease, is confirmed by enzymatic assays in serum, leukocytes, fibroblasts, or a combination of these. The diagnosis of Niemann–Pick C disease requires measurement of cellular cholesterol esterification and documentation of a characteristic pattern of filipin–cholesterol staining in cultured fibroblasts during LDL uptake. Analysis of DNA mutations may be helpful for the diagnosis of Niemann–Pick C disease, Gaucher disease, and some other conditions, and it will become increasingly available for other conditions. An imperfect genotype–phenotype correlation impedes the use of mutation analysis as a prognostic tool. In addition, prenatal diagnosis is available for most LSDs through the use of enzyme assays performed on amniocytes or chorionic villus cells or measurements of levels of stored substrate in cultured cells or amniotic fluid. As mutation analysis becomes more prevalent, it will increasingly substitute for biochemical and enzymatic methods.

These conditions must also be considered in the dying infant, and the neonatologist must be prepared to request the appropriate samples for diagnosis at the time of death. In surviving patients, treatment and management must be considered. All the LSDs are chronic and progressive conditions for which there is no curative treatment. Gene transfer therapy holds promise but is not currently available for LSDs. With few exceptions, current standard medical management is supportive and palliative. Patients must be continually reassessed for evidence of disease progression and associated complications. These complications manifest themselves at variable

ages and can include hydrocephalus, valvular heart disease, joint limitation, and obstructive airway disease.

For several disorders, particularly neonatal Gaucher disease and Niemann–Pick C disease, splenectomy may be indicated to relieve severe anemia and thrombocytopenia. This procedure enhances the risk of serious infections, and it can accelerate the progression of disease at other sites. Patients with Krabbe disease may have significant pain of radiculopathy and spasms, and alleviation of that pain is important for the patient's comfort. The administration of a glutamic acid transaminase inhibitor, vigabatrin, has been used in a small number of patients with Krabbe disease, because part of the disease may involve a secondary deficiency of γ -aminobutyric acid (Barth, 1995). Low-dose morphine has also been reported to reduce the irritability associated with this disorder (Stewart et al., 2001).

Enzyme replacement therapy (ERT) with imiglucerase (Cerezyme®, Sanofi Genzyme), a recombinant enzyme, is available for Gaucher disease. Although ERT has successfully reversed many of the systemic manifestations of the disease, it has been suggested that ERT should not be given to patients with Gaucher disease type 2 who already have severe neurologic signs, because no substantial relief has been demonstrated to occur in the neurologic symptoms of patients treated (Erikson et al., 1993; McCabe et al., 1996). ERT should be discussed with families, and in some instances it may be appropriate to provide ERT until it has been established that the patient does not have the less severe form of Gaucher disease type 3 (Weiss et al., 2015).

HSCT has been tried for a variety of LSDs. The rationale for the procedure is that circulating blood cells derived from the transplanted marrow become a source of the missing enzyme. Results of HSCT in disorders of GAGs show that after successful engraftment, leukocyte and liver tissue enzyme activity normalizes, organomegaly decreases, and joint mobility increases. Skeletal abnormalities stabilize but do not abate. Whether brain function can be improved in patients with CNS disease remains questionable. Some patients maintain their learning capability or intelligence quotient, but others continue to deteriorate. Clinical experience and studies in animal models indicate that HSCT before the onset of neurologic symptoms can prevent or delay the occurrence of symptoms, whereas there is no clear benefit if transplantation is performed when symptoms are already present (Hoogerbrugge et al., 1995). HSCT in patients with nonneuropathic Gaucher disease can result in complete disappearance of all symptoms; however, the procedure is associated with significant risks (Hoogerbrugge et al., 1995) that must be balanced against lifelong ERT. Currently it is unclear to what extent patients with Gaucher disease type 2 would benefit from transplantation (Weiss et al., 2015); therefore it is generally not recommended.

HSCT has also been attempted in a small number of patients with infantile Krabbe disease, Farber lipogranulomatosis, and Niemann–Pick A disease. The outcome after transplantation for these few patients has been poor, with continued disease progression and death. Success may depend on treatments started very early in life before the onset of neurologic signs of diseases (Escobar et al., 2005, 2006). Krivit et al. (2000) reported successful long-term bone marrow engraftment in a patient with Wolman disease that resulted in normalization of peripheral leukocyte lysosomal acid lipase enzyme activity. The patient's diarrhea resolved; cholesterol, triglyceride, and liver function values normalized, and the patient attained developmental milestones. LSDs are not all equally amenable to HSCT, and the use of HSCT as a treatment modality for most LSDs remains uncertain. In a small number of cases,

HSCT has been performed in utero after prenatal diagnosis showing an affected fetus, and experimental protocols are available for families who wish to pursue this option.

The preferred treatment to reduce the accumulation of storage material in intestine and phagocytes in lysosomal acid lipase deficiency is ERT (Burton et al., 2015; Rader 2015), and there is now a trial using sebelipase alfa to treat Wolman disease (www.ClinicalTrials.gov identifier NCT01757184).

Congenital Disorders of Glycosylation

Etiology

CDGs are a group of more than 100 genetic diseases that involve various defects in the process of modifying proteins, lipids, or other biomolecules with glycans (sugar molecules or chains) (Freeze et al., 2014). Glycosylation, the addition of glycans to biomolecules, is essential to many biologic processes, such as aiding with correct folding, protecting against premature destruction, directing intracellular localization and transport, and modifying the biologic function of these biomolecules.

The first CDG discovered (PMM2-CDG) was described by Jaak Jaeken in 1980 and was initially termed *carbohydrate-deficient glycoprotein syndrome* because of abnormalities seen in multiple serum glycoproteins in the affected individuals (Jaeken et al., 1980; Jaeken et al., 1984). When several more human glycosylation disorders were identified, this group of disorders was renamed *congenital disorders of glycosylation*. The decision was made to designate the types of CDG into either a group I or a group II disorder on the basis of the transferrin pattern obtained by isoelectric focusing, with specific diagnoses alphabetized consecutively as they were identified (i.e., CDG Ia, Ib, Ic, IIa, IIb, etc.) (Aebi et al., 1999). Improved molecular diagnostics expanded the definition of CDGs to include genetic diseases that primarily disrupt the process of formation of any glycoconjugate (i.e., glycoproteins, glycolipids, glycosaminoglycan, etc.), resulting in an exponential growth of the number of pathways and individual disorders (Jaeken, 2010). In 2009 the nomenclature was updated, and currently specific CDG types are named starting with the affected gene symbol (not in italics) followed by CDG (e.g., CDG Ia is now PMM2-CDG) (Jaeken et al., 2009).

It is estimated that approximately 2% (~400) of our genes encode proteins involved with the glycosylation process, which occurs in a variety of locations within the cell, including the cytosol, endoplasmic reticulum, and Golgi apparatus. The underlying mechanism for the clinical manifestations of most of these disorders is still unclear. Given the complexity of glycosylation, there are multiple methods to subdivide these disorders. One classification schema sorts CDGs into protein N-linked glycosylation defects, protein O-linked glycosylation defects, glycosylphosphatidylinositol (GPI) anchor glycosylation defects, lipid glycosylation defects, and defects in multiple glycosylation and other pathways (Jaeken, 2011). In this chapter we use this classification method to help organize our discussion of the CDGs that manifest themselves in the neonatal period.

Clinical Presentations

Because so many biologic functions are dependent on the correct glycosylation, the phenotypic spectrum of CDG defects is extremely broad and ranges from mild to severe disease and from a single-organ system to multisystem disease. Clinical features alone are insufficient

to define the CDG type. A CDG should be considered in any unexplained clinical condition, but especially in multiorgan disease with neurologic involvement (Table 23.2).

N-Linked Protein Glycosylation Defects

Etiology

N-linked protein glycosylation, the process involved with attaching glycans to the asparagine residue of target proteins, was the first discovered and is the best understood glycosylation pathway in humans. Classically, these disorders were divided into two categories: type I, which results in defects in *N*-glycan assembly, and type II, which results from defects in *N*-glycan processing. The initial assembly steps of *N*-glycosylation occur on the endoplasmic reticulum membrane, where sugars are attached in a stepwise manner to dolichol phosphate to form a lipid-linked oligosaccharide. Sugars are donated by an activated nucleotide sugar (uridine diphosphate-*N*-acetylglucosamine and guanosine diphosphate-mannose), with the attached nucleotide providing the necessary energy for the transfer of the sugar to the lipid-linked oligosaccharide. This oligosaccharide is then transferred to the nascent protein cotranslationally. Once the oligosaccharide chain has been transferred to the protein, further processing occurs. The oligosaccharide is then transported to the Golgi apparatus, where further processing occurs. Different types of CDGs have been found in affected individuals who have defective enzymes in individual steps of this complex pathway, including the enzymes that form the dolichol backbone, transfer single sugars to the growing chain, interconvert activated monosaccharides, and transfer the oligosaccharide from dolichol to protein (Hennet, 2012; Jaeken, 2012).

Clinical Features

N-linked glycosylation defects encompass a large number of disorders. Taken together these several dozen disorders are typically multisystemic with significant neurologic involvement with the notable exception of MPI-CDG, in which development can be normal (Sparks and Krasnewich, 1993). The most common perinatal findings include hypotonia, nonspecific dysmorphic features (mostly without inverted nipples or abnormal fat pads), feeding problems with growth delay, hepatopathy with elevated levels of transaminases, and abnormal coagulation profiles. Discriminating findings include neonatal hemorrhages (including cerebral hemorrhage) and thrombotic events, strabismus, nystagmus and other ophthalmologic findings, neonatal seizures, and an abnormal thyroid function screening result (Funke et al., 2013). Transferrin glycosylation analysis previously performed by isoelectric profiling and now performed by mass spectrometry methods shows an abnormal glycosylation pattern in many, but not all, of these disorders.

Three disorders warrant special mention. PMM2-CDG (CDG Ia) is the classic and most common presentation, and many other N-linked CDGs mirror its presentation. Most affected infants appear normal at birth. In infancy, patients with PMM2-CDG can exhibit dysmorphic features, strabismus, nystagmus, and feeding difficulties; subsequently patients may exhibit growth failure, hypotonia, lipocutaneous abnormalities (including prominent fat pads on the buttocks), coagulopathy with thrombosis and bleeding, pericardial effusion, and mild to moderate hepatomegaly and hepatopathy. Approximately 20% of patients die during the first year of life after a course of severe fluid imbalance and sometimes anasarca in response to infection or their underlying glycosylation disorder (Grunewald, 2009). Having survived infancy, patients with PMM2-CDG can live into their seventh and eighth decades. Later manifestations include retinitis pigmentosa or retinal

degeneration, pericardial effusion, renal cysts, coagulopathy, stroke-like episodes, thrombotic disease, cerebral and olivopontocerebellar hypoplasia, ataxia, peripheral neuropathy followed by lower extremity atrophy, and hypogonadism. In general, patients have an extroverted disposition and happy appearance (Krasnewich et al., 2007). MPI-CDG (CDG Ib) stands out in this group of disorders because patients with MPI-CDG can have normal development, and mannose is a known targeted therapy. These individuals can experience vomiting, protein-losing enteropathy, and progressive liver fibrosis (Jaeken and Matthijs, 2007) but can also survive to adulthood. NGLY1-CDDG is the first described disorder of N-linked deglycosylation. It presents with hepatopathy, alacrima (lack of tears), intellectual disability, and movement disorder. In infancy many times the first symptom is poor feeding and motor delay with hyperkinesia (Need et al., 2012).

O-Linked Protein Glycosylation Defects

Etiology

O-glycosylation consists of attachment of a monosaccharide (mannose, fructose, or xylose) or the assembly of a glycan and its attachment to a serine or threonine residue of a target protein. O-glycosylation differs from N-glycosylation in that it does not occur at the same time as the protein is being translated but occurs posttranslationally, exclusively in the Golgi apparatus, without further processing (Jaeken and Matthijs, 2007). O-glycosylation can be classified according to the type of sugar that is attached to the serine or threonine. Examples of O-glycosylation include O-mannosylation, O-xylosylation, and O-fucosylation.

Clinical Features

The clinical features differ significantly depending on which type of O-glycosylation is defective. Deficiency of *O*-*N*-acetylglucosamine linkage can lead to familial tumoral calcinosis with phosphatemia and massive calcium deposits in the skin and subcutaneous tissues (Freeze and Schachter, 2009). A defect in O-fucosylation has been shown to lead to Peters plus syndrome characterized by anterior eye chamber defects, disproportionate short stature, developmental delay, and cleft lip and/or palate (Lesnik Oberstein et al., 2006). Defects in O-xylosylation will lead to defective anchoring of GAGs to proteins and thus impaired proteoglycan formation. Defective O-xylosylation can lead to progeroid-type Ehlers–Danlos syndrome characterized by failure to thrive, loose skin, skeletal abnormalities, hypotonia, and hypermobile joints. Defects in forming heparin sulfate, also attached to proteins via O-xylosylation, cause congenital exostosis, an autosomal dominant disorder where patients have bony outgrowths usually at the growth plate of the long bones. Defective cartilage proteoglycan sulfation leads to achondrogenesis, diastrophic dystrophy, and atelosteogenesis that manifest themselves as symptoms in cartilage and bone such as cleft palate and club feet and in the severest cases lead to perinatal death from respiratory insufficiency (Freeze and Schachter, 2009).

Additionally, there are more than a dozen different genetic disorders that lead to a defect in O-mannosylation (Endo, 2015). O-mannosylation defects lead to hypoglycosylation of α -dystroglycan, an important glycoprotein needed to link the intracellular cytoskeleton of muscle to the extracellular matrix. These disorders, collectively referred to as α -dystroglycanopathies, have a wide spectrum of clinical severity and encompass previously described disorders, ranging from Walker–Warburg syndrome, muscle–eye–brain disease, and Fukuyama congenital muscular dystrophy to limb–girdle muscular dystrophy (Mercuri et al., 2009; Topaloglu, 2009). In the neonate, clinical features involve the triad of muscle,

eye, and brain, and may include hypotonia; muscle weakness; microcornea; microphthalmia; pale, hypoplastic or absent optic nerves; colobomas; cataracts; iris hypoplasia; glaucoma; retinal dysplasia or detachment; and brain structural abnormalities, including hydrocephalus, brainstem hypoplasia, cerebellar cysts, cobblestone lissencephaly, polymicrogyria, cerebellar vermis and hemisphere atrophy, hypoplasia of the pyramidal tracts, and absence of the corpus callosum. There is no specific blood or urine biochemical marker available for this group of disorders. Elevated creatine kinase level is frequently noted. Muscle biopsy with specialized immunohistochemical staining may show deficient glycosylated α -dystroglycan and normal β -dystroglycan level. Molecular testing is needed to confirm the specific type (Sparks et al., 1993).

Combined Glycosylation Defects

Etiology

Combined N-glycosylation and O-glycosylation and other glycosylation defects are important because they appear to affect trafficking in the glycosylation machinery (Grünwald, 2007). Several of these disorders involve defects in channels involved in activated sugar-nucleotide transport (SLCx-CDG). Some affect vesicular transport (COGx-CDG) in general. Others affect the process of sugar activation (attaching nucleotides to monosaccharides so that they can be used for glycosylation). Yet others cause abnormalities in the Golgi apparatus structure (TMemx-CDG), which needs to be intact for glycosylation to proceed (Ungar et al., 2002).

Clinical Features

In the neonate the most frequent presenting symptoms include neonatal microcephaly; neonatal seizures; strabismus; hypotonia; dysmorphic features, especially cutis laxa; feeding problems with growth delay; and hepatic involvement (Funke et al., 2013). Again, encompassing a very large group of disorders, the presentations are very heterogeneous and include not only multisystemic diseases with the aforementioned symptoms but also single system disorders such as congenital dyserythropoietic anemia type II due to SEC23B-CDG.

Glycosylphosphatidylinositol Anchor Glycosylation Defects

Etiology

The biosynthesis and attachment of GPI anchors to proteins occur in the endoplasmic reticulum and Golgi apparatus and involve 11 steps and at least 27 genes (Kinoshita et al., 2008). To date, inherited loss-of-function mutations in more than a dozen of these genes have been implicated in human disease. GPI anchors are attached during posttranslational modification and allow these proteins to attach to the outer leaflet of the cell membrane and face the extracellular environment. This permits these proteins to participate in processes such as signal transduction and immune response (Paulick and Bertozzi, 2008; Ferguson et al., 2009).

Clinical Features

Typically, individuals affected with GPI anchor disorders have a severe phenotype and present in infancy with epilepsy, intellectual disability, and multiple congenital anomalies, including heart, skeletal (especially abnormalities in phalanges), endocrine, ophthalmologic, and facial anomalies, with possible abnormalities in alkaline phosphatase levels depending on the specific diagnosis (Jezela-Stanek et al., 2016). Although there is no standard blood or urine biomarker, flow cytometry markers show promise to be effective biomarkers in many of these disorders (Freeze et al., 2012).

Lipid Glycosylation Defects

To date, three disorders of lipid glycosylation have been described. SIAT9-CDG, also known as Amish infantile epilepsy, was the first identified and is caused by a defect of lactosylceramide α -2,3-sialyltransferase (GM₃ synthase) (Jaeken, 2006). This enzyme catalyzes the initial step in the biosynthesis of most complex gangliosides from lactosylceramide (Jaeken and Matthijs, 2007). The defect causes accumulation of lactosylceramide associated with decreased levels of gangliosides (Jaeken, 2006). Individuals with this disorder present with infantile-onset epilepsy with developmental stagnation, blindness, poor feeding, vomiting, failure to thrive, later-onset “salt and pepper” macules, and variable survival (Boccuto et al., 2014). ST3GAL-CDG is a cause of West syndrome (Freeze et al., 2015). B4GALNT1-CDG, also known as spastic paraplegia 26, is also a defect in ganglioside biosynthesis. However, onset of symptoms including gait abnormalities and central and peripheral nervous system involvement typically occurs after the neonatal period, in the first 2 decades of life (Boukhris et al., 2013).

Diagnosis

CDG should be considered in young infants with several of the following features:

- Neurologic signs, including hypotonia, hyporeflexia, or seizures
- Ophthalmic signs, including abnormal eye movements, cataracts, optic nerve atrophy, retinitis pigmentosa, or glaucoma
- Hepatic and GI signs, including ascites or hydrops, hepatomegaly, diarrhea, and protein-losing enteropathy
- Endocrinologic signs, including hyperinsulinemic hypoglycemia and hypothyroidism
- Hematologic signs, including thrombosis or coagulopathy with factor deficiency
- Signs of renal or cardiac disease
- Musculoskeletal signs, including congenital muscular dystrophy, and congenital joint contractures
- Dysmorphic features, microcephaly, or abnormal skin findings

Serum transferrin isoform analysis is the most available screening method, but it detects only N-glycosylation and some mixed glycosylation defects. Until about 2000, transferrin screening was achieved by isoelectric focusing of transferrin; failure to correctly synthesize the N-linked glycans alters the charge on serum transferrin and consequently its migration in an electrophoretic field. Since then, however, mass spectrometry methods, capable of identifying individual oligosaccharides and complete glycans by mass and charge, have replaced transferrin isoelectric focusing as the standard method for screening patients for CDGs (Sturiale et al., 2011). Transferrin and glycan analysis may yield false positive results in galactosemia, inborn errors of fructose metabolism, alcohol consumption, certain bacterial (neuraminidase-producing) infections, and in cases of mutations in transferrin itself. False negatives can occur in the first 3 weeks of life (Freeze et al., 2012). There are also reported cases where initially abnormal transferrin glycosylation normalizes without relief of symptoms. There are also N-linked defects known to not show transferrin isoform abnormalities (MOGS-CDG, TUSC3-CDG, SLC35A1-CDG, SLC35C1-CDG) (He et al., 2012).

Apolipoprotein CIII glycan analysis has been used in the screening of some mixed and O-glycosylation disorders. Urine oligosaccharide screening is useful in detecting MOGS-CDG. Many defects

in GPI synthesis can be identified by flow cytometry of GPI-anchored proteins, such as FLAER or CD59 on leukocytes. Not all subtypes of CDGs have convenient biochemical markers; for example, screening for congenital muscular dystrophies caused by defective O-mannosylation requires a muscle biopsy with the use of monoclonal antibodies directed against the glycan (He et al., 2012). There are also no simple markers for defects in GAG biosynthesis. Since the advent of next-generation sequencing and exome analysis, most CDGs have been diagnosed molecularly (Timal et al., 2012). Once variants are identified in the specific gene, if novel, the functional consequence of the mutation can be confirmed by enzymatic assays in peripheral blood leukocytes or cultured fibroblasts for PMM2-CDG and MPI-CDG and on a research basis for other types. Prenatal diagnosis is possible in all types of CDG for which the molecular defect is known (Grunewald, 2007). The vast majority of CDGs are autosomal recessive disorders; POGlut1-CDG and POFUT1-CDG (Dowling–Degos disease), EXT1&2-CDG (hereditary multiple exostoses syndrome), and SEC63-CDG and PRKCSH-CDG (polycystic liver disease) are autosomal dominant; C1GALT1C1-CDG, PIGA-CDG, SSR4-CDG, SLC35A2-CDG, ALG13-CDG, and MAGT1-CDG are X-linked.

Treatment, Management, and Prognosis

A specific treatment is available for only a minority of CDGs. MPI-CDG can be treated with orally administered mannose (Thiel and Korner, 2013), which can help significantly with the protein-losing enteropathy but does not necessarily halt the progression of the liver disease. Heparin has also been used for protein-losing enteropathy in MPI-CDG (de Lonlay and Seta, 2009). In SLC35C1-CDG, some patients respond to oral fucose supplementation; this treatment is effective only with regard to the typical recurrent infections with hyperleukocytosis and does not correct the neurodevelopmental aspects (Marquardt et al., 1999). In PIGM-CDG, butyrate has been shown to control the seizures in some cases (Almeida et al., 2007). There are ongoing trials to assess the efficacy of galactose in PGM1-CDG, and preliminary findings show promise that this therapy may alleviate the hypoglycemia, coagulopathy, and endocrinopathy seen in this disorder (Morava, 2014). The treatment and management of other types of CDGs are primarily supportive and palliative. In infancy, evidence of multisystem involvement and the resulting complications must be treated promptly. There is substantial mortality in the first years of life because of severe infection or vital organ failure (Jaeken, 2006; Grunewald, 2007).

Peroxisomal Disorders

Peroxisomes are small, evolutionarily conserved, single membrane-bound cellular organelles that contain no internal structure or DNA and are characterized by an electron-dense core and a homogeneous matrix. Peroxisomes are found in all cells and tissues except mature erythrocytes and are in highest concentration in the liver and kidneys. They are formed predominantly by growth and division of preexisting peroxisomes, but they can also arise de novo from peroxisomal vesicles that originate from specialized compartments of the endoplasmic reticulum (Waterham and Ebberink, 2012; Braverman et al., 2016; Waterham et al., 2016). Their half-life is 1.5–2 days before they are randomly destroyed by autophagy. All peroxisomal proteins are encoded by nuclear genes, synthesized in cytosol, and imported posttranslationally

into the peroxisome (Waterham and Ebberink, 2012). The import of proteins into the peroxisome is mediated by specific targeting sequences known as peroxisomal targeting sequences (Waterham et al., 2016).

Peroxisomes contain enzymes that use oxygen to oxidize a variety of substrates, thereby forming peroxide. The peroxide is decomposed within the organelle by the enzyme catalase to water. This process protects the cell against peroxide damage through compartmentalization of peroxide metabolism within the organelle. Peroxisomes can also function to dispose of excess reducing equivalents and may contribute to thermogenesis, producing heat from cellular respiration (Gould et al., 2001).

More than 70 enzymes have been found within peroxisomes (Braverman et al., 2016). The proteins have multiple functions, both synthetic and degradative (Braverman et al., 2016; Waterham et al., 2016). The primary synthetic functions are plasmalogen synthesis and bile acid and docosahexanoic acid formation. Plasmalogens constitute 5%–20% of phospholipids in cell membranes and 80%–90% of phospholipids in myelin. They are involved in platelet activation and may also protect cells against oxidative stress. Degradative functions include (1) β -oxidation of very long chain fatty acids (VLCFAs) ($\geq C_{23}$), fatty acids (down to C_8 to C_6), long-chain dicarboxylic acids, prostaglandins, and polyunsaturated fatty acids; (2) oxidation of bile acid intermediates, pipercolic acid and glutaric acid (intermediates in lysine metabolism), and phytanic acid; (3) deamination of D-amino acids and L-amino acids; (4) metabolism of glycolate to glyoxylate; (5) polyamine degradation (spermine and spermidine); and (6) ethanol clearance. At least 16 conditions caused by peroxisomal enzyme deficiencies have been confirmed (Klouwier et al., 2015; Braverman et al., 2016; Waterham et al., 2016).

Peroxisomal disorders constitute a clinically and biochemically heterogeneous group of inherited diseases that result from the absence or dysfunction of one or more peroxisomal enzymes. Disorders in which more than one enzyme is affected are collectively termed *peroxisomal biogenesis disorders* (PBDs). Disorders in which only one enzyme is affected encompass the remaining known disorders. All but one are inherited in an autosomal recessive manner. The pathophysiologic features apparently involve either deficiency of necessary products of peroxisomal metabolism or excess of unmetabolized substrates. Disorders with similar biochemical defects may have markedly different clinical features, and disorders with similar clinical features may be associated with different biochemical findings. General features of peroxisomal disorders, each of which can be evident in the newborn period, are as follows:

- Dysmorphic craniofacial features
- Neurologic dysfunction, primarily consisting of severe hypotonia, possibly associated with hypertonia of extremities, seizures, and abnormalities in neuronal migration
- Hepatodigestive dysfunction, including hepatomegaly, cholestasis, prolonged hyperbilirubinemia, and feeding difficulties
- Rhizomelic shortening of the limbs, stippled calcifications of epiphyses, and renal cysts

In this section we discuss the peroxisomal disorders that can manifest themselves in the newborn period.

Disorders of Peroxisomal Biogenesis

Conditions in which multiple peroxisomal enzymes are affected can result from a disturbance of biogenesis of the organelle. Peroxisomal assembly includes matrix protein import, synthesis of new organelles, and fusion of existing organelles. The coordinated

activity of 16 PEX proteins, or peroxins, encoded by their corresponding genes is required for this process (Braverman et al., 2013). The PEX genes responsible for disease in most human patients are known, with more than 60% of patients with PBD having mutations in *PEX1*; the second most commonly involved gene is *PEX6* (Waterham et al., 2012; Braverman et al., 2013; Braverman et al., 2016). The overall incidence of PBD is estimated to be approximately 1 in 50,000 newborns (Klouwer et al., 2015; Braverman et al., 2016).

Zellweger syndrome is the prototype of neonatal peroxisomal disease. It is a disorder of peroxisome biogenesis caused by failure to import newly synthesized peroxisomal proteins into the peroxisome. The proteins remain in the cytosol, where they are rapidly degraded. In this condition, peroxisomes are absent from liver hepatocytes or exist as “ghosts.” Neonatal adrenoleukodystrophy and infantile Refsum disease are also disorders of peroxisome biogenesis in which, as in Zellweger syndrome, disruption of function of more than one peroxisomal enzyme is demonstrable. A few residual peroxisomes, however, may be seen in the liver. These disorders represent a continuum of clinical severity, and the term *Zellweger spectrum disorders* (ZSDs) is now suggested (Braverman et al., 2013; Braverman et al., 2016). Features common across the spectrum include liver disease, variable neurologic dysfunction, developmental delay, retinopathy, neurosensory hearing loss, and adrenocortical dysfunction (Poll-The and Gärtner, 2012; Klouwer et al., 2015). Rhizomelic chondrodysplasia punctata, types 1 and 5, are caused by a defect in a subset of peroxisomal enzymes resulting from mutations in the *PEX7* gene and the *PEX5L* isoform respectively. In these disorders, liver peroxisomes are demonstrable and normal in number, but their distribution and structure are abnormal. A new category of disorders, referred to as *peroxisomal fission defects*, has also been recognized. Peroxisomal fission defects are disorders caused by defects in proteins known to be involved with the proliferation and division of peroxisomes (Mff, Fisl, PEX11, DLP1) (Waterham et al., 2007; Schrader et al., 2012; Waterham and Ebberink, 2012; Waterham et al., 2016). Finally, Heimler syndrome, a rare recessive disorder, typically presenting in young childhood with sensorineural hearing loss, amelogenesis imperfecta, nail abnormalities, and retinal pigmentation, was recognized as a mild PBD disorder involving mutations in *PEX1* and *PEX6* (Ratbi et al., 2015).

Zellweger Syndrome

Zellweger syndrome is most often evident at birth, with affected newborns having dysmorphic facial features including large fontanels, high forehead, flat occiput, epicanthus, hypertelorism, upward-slanting palpebral fissures, hypoplastic supraorbital ridges, abnormal ears, severe weakness and hypotonia, hepatomegaly, multicystic kidneys, and congenital heart disease. Seizures, feeding difficulties, and postnatal growth failure soon manifest themselves. Ophthalmologic examination may detect cataracts, corneal clouding, glaucoma, optic atrophy, retinitis pigmentosa, and Brushfield spots. Somatic sensory evoked responses and electroretinograms are abnormal. Hearing assessment often shows an abnormal brainstem auditory evoked response consistent with sensorineural hearing loss. Skeletal radiographs demonstrate epiphyseal stippling, and cranial imaging shows leukodystrophy and neuronal migration abnormalities. Hepatic cirrhosis and severe psychomotor retardation occur later. Laboratory analysis may demonstrate abnormal liver function values, hyperbilirubinemia, or hypoprothrombinemia. Death usually occurs within the first year of life, the average life span being 12.5 weeks.

Neonatal Adrenoleukodystrophy

Clinically, neonatal adrenoleukodystrophy is similar to, but less severe than, Zellweger syndrome. Differences include less dysmorphism, absence of chondrodysplasia punctata and renal cysts, and fewer neuronal and gray matter changes. Patients with neonatal adrenoleukodystrophy may have striking white matter disease, however, and often show degenerative changes in adrenal glands. They also have slow psychomotor development followed by neurodegeneration that usually begins before the end of the first year of life. Disease progression is slower than that observed in Zellweger syndrome, and longer survival is usual, to an average of approximately 15 months of age or into the teen years (Waterham et al., 2016).

Infantile Refsum Disease

Patients with infantile Refsum disease also have relatively mild dysmorphic features, such as epicanthic folds, midface hypoplasia with low-set ears, and mild hypotonia. Early neurodevelopment is normal, possibly up to 6 months of age, but then slow deterioration begins. Later, sensorineural hearing loss (100%), anosmia, retinitis pigmentosa, hepatomegaly with impaired function, and severe cognitive impairment are evident. Patients learn to walk, although their gait may be ataxic and broad based. Diarrhea and failure to thrive may also be seen. Chondrodysplasia punctata and renal cysts are absent. Neuronal migration defects are minor and adrenal hypoplasia occurs. The life span of patients with infantile Refsum disease ranges from 3 to 11 years or into adulthood.

Rhizomelic Chondrodysplasia Punctata

Patients with defects in the biosynthesis of ether phospholipids present with rhizomelic chondrodysplasia punctata. Five genetically distinct, but clinically indistinguishable, groups exist, three of which are single enzyme defects (types 2, 3, and 4) and the other two of which are peroxisomal biogenesis defects (types 1 and 5) (Waterham et al., 2016). Patients with rhizomelic chondrodysplasia punctata at birth have facial dysmorphism, microcephaly, cataracts, rhizomelic shortening of extremities with prominent stippling, and coronal clefting of vertebral bodies. The chondrodysplasia punctata is more widespread than in Zellweger syndrome and may involve extraskel-etal tissues. Infants with this disorder have severe psychomotor retardation from birth onward and severe failure to thrive. In addition, patients may have joint contractures, and 25% experience ichthyosis. Neuronal migration is normal. The life span is usually less than 1 year.

Peroxisomal Fission Defects

The first described patient with a peroxisomal fission defect was a severely affected female patient with mitochondrial encephalopathy who died at 1 month of age (Waterham et al., 2007). She was noted to have microcephaly, mild dysmorphic features, truncal hypotonia, absent deep tendon reflexes, optic atrophy, failure to thrive, abnormal brain development, and severe developmental delay. She had elevated peripheral and central lactic acid and alanine levels, mildly elevated VLCFA levels, and abnormal-appearing peroxisomes and mitochondria in fibroblasts but normal oxidative phosphorylation values in fibroblasts and skeletal muscle specimens (Waterham et al., 2007). Evaluation revealed a peroxisomal and mitochondrial fission defect with a heterozygous, dominant-negative mutation in the dynamin-like protein 1 gene (*DLP1*) (Waterham et al., 2007). Additional patients with *DLP1* mutations have been described (Vanstone et al., 2016; Chao et al., 2016; Sheffer et al.,

2016). Patients may not show significant peroxisomal or biochemical abnormalities.

Single Peroxisomal Enzyme Defects

Of patients with suspected ZSD and elevated VLCFA levels, approximately 10%–15% will have a single enzyme defect (Braverman et al., 2013; Braverman et al., 2016). To date, three childhood disorders of peroxisomal fatty acid β -oxidation have been defined: D-bifunctional protein deficiency, acyl-CoA oxidase deficiency, and 2-methylacyl-CoA racemase deficiency (Waterham et al., 2016). The clinical presentation resembles that of biogenesis disorders. Previously, an isolated case of a fourth disorder, peroxisomal thiolase deficiency, was described (Goldfischer et al., 1986). On reinvestigation, however, this case was identified as D-bifunctional protein deficiency (Ferdinandusse et al., 2002).

D-Bifunctional Protein Deficiency

D-bifunctional protein deficiency is a rare single peroxisomal enzyme defect that results in a phenotype similar to Zellweger syndrome. It is caused by mutations in the *HSD17B4* gene encoding 17 β -estradiol dehydrogenase, an enzyme involved in β -oxidation of VLCFAs and branched-chain fatty acids, including pristanic acid and bile acid intermediates, resulting in accumulation of VLCFAs, pristanic acid, and dihydroxycholestanoic acid and trihydroxycholestanoic acid (Shimozawa et al., 2011; Waterham et al., 2016). In general, children have severe CNS involvement consisting of profound hypotonia, uncontrolled seizures, and failure to acquire any significant developmental milestones. Children are usually born at term without evidence of intrauterine growth restriction. Dysmorphic features, similar to those seen in Zellweger syndrome, are notable in most children. In most cases, neuronal migration is disturbed, with areas of polymicrogyria and heterotopic neurons in the cerebrum and cerebellum. Death generally occurs before 1 year of age, but survival to at least 3 years of age is possible.

Acyl Coenzyme A Oxidase Deficiency

Acyl-CoA oxidase deficiency, also called *pseudoneonatal adrenoleukodystrophy*, is a rare, neuroinflammatory, neurodegenerative disorder (El Hajj et al., 2012; Wang et al., 2015). It is caused by mutations in *ACOX1* exclusively involved in the β -oxidation of straight-chain fatty acids resulting in the accumulation of VLCFAs (El Hajj et al., 2012; Waterham et al., 2016). Patients exhibit global hypotonia, deafness, and delayed developmental milestones with or without facial dysmorphic features. Patients may demonstrate early developmental skills but then show regression of skills typically between 24 and 48 months of age (Wang et al., 2015). Retinopathy with extinguished electroretinograms, nystagmus, optic atrophy, failure to thrive, hepatomegaly, areflexia, seizures, and white matter demyelination have also been reported (Poll-The et al., 1988; Carrozzo et al., 2008; El Hajj et al., 2012).

2-Methylacyl Coenzyme A Racemase Deficiency

2-Methylacyl-CoA racemase (AMACR) deficiency is a rare disorder caused by mutations in the *AMACR* gene encoding the enzyme 2-methylacyl-CoA racemase. The enzyme catalyzes the isomerization of fatty acids with a methyl group in the *R* configuration to the corresponding *S* configuration, an obligatory reaction in the steps leading to peroxisomal β -oxidation. This results in impaired bile acid synthesis and pristanic acid metabolism and subsequent accumulation of pristanic acid, (25*R*)-trihydroxycholestanoic acid, and (25*R*)-dihydroxycholestanoic acid (Setchell et al., 2003). Most

patients present with an adult-onset ataxia and sensory neuropathy; however, an infantile presentation with cholestatic liver disease, coagulopathy, and fat-soluble vitamin deficiency has been reported (Setchell et al., 2003; Waterham et al., 2016).

X-Linked Adrenoleukodystrophy

X-linked adrenoleukodystrophy (X-ALD) is the most common peroxisomal disorder, with an estimated incidence of 1 in 17,000 (Waterham et al., 2016). It is caused by the altered function of the membrane-bound protein ABCD1, which predominantly catalyzes the import of straight-chain VLCFAs into peroxisomes (Waterham et al., 2016). It does not usually present in the newborn period; however, contiguous *ABCD1 DXS1357E* deletion syndrome, caused by a contiguous gene deletion of *ABCD1* and its upstream gene *DXS1357E*, may. Four male patients have been reported with profound neonatal hypotonia, severe growth and developmental retardation, cholestatic liver disease, accumulation of VLCFAs, and death within the first year of life (Corzo et al., 2002; Shimozawa et al., 2011; Iwasa et al., 2013).

Diagnosis, Management, and Prognosis

The key to diagnosing peroxisomal disorders is a high index of suspicion. Peroxisomal disorders should be considered in newborns with dysmorphic facial features, skeletal abnormalities, shortened proximal limbs, neurologic abnormalities (including hypotonia or hypertonia), ocular abnormalities, and hepatic and renal abnormalities. Babies with abnormal vision, hearing, or somatosensory evoked potentials should also be considered for these diagnoses.

Peroxisomal disorders are not associated with acute metabolic derangements or abnormal routine laboratory test findings. Measurements of the levels of VLCFAs, phytanic acid, pristanic acid, pipecolic acid, bile acid intermediates, and plasmalogens are required for diagnosis. Zellweger syndrome is associated with elevations of the levels of VLCFAs, phytanic acid, pipecolic acid, and bile acid intermediates and a decrease in plasmalogen synthesis. Neonatal adrenoleukodystrophy and infantile Refsum disease have similar biochemical findings; however, the defect in plasmalogen synthesis and the degree of VLCFA accumulation are less severe. Laboratory findings in rhizomelic chondrodysplasia punctata include elevations of the levels of phytanic and pipecolic acids, a decrease in the levels of plasmalogens, and normal levels of VLCFAs and bile acid intermediates. Therefore screening that uses only levels of VLCFAs fails to detect rhizomelic chondrodysplasia punctata. Also, a small number of patients with mutations in PEX genes have been identified with mild or absent elevations in VLCFA levels (Braverman et al., 2016). D-bifunctional protein deficiency is associated with deficient oxidation of C23:0 and pristanic acid, leading to elevations of the levels of pristanic acid and, to a lesser extent, phytanic acid. This deficiency results in an elevated pristanic acid to phytanic acid ratio, which is generally not elevated in PBD. Abnormal VLCFA levels and elevations of the levels of varanic acid, an intermediate metabolite in β -oxidation, are also seen. Accumulation of bile acid intermediates is a variable finding.

Abnormalities in the levels of phytanic acid and plasmalogens are age dependent. The elevation of the levels of phytanic and pristanic acids might not be demonstrable in newborns not consuming dairy products or other dietary sources of these fatty acids, and reduction in red blood cell plasmalogen levels may not be evident in children older than 20 weeks (Gould et al., 2001; Lee and Raymond, 2013; Braverman et al., 2016). Pipecolic acid levels are more likely to be abnormal in the urine of newborns and more

abnormal in plasma at later ages (Braverman et al., 2016). A ketogenic diet may elevate VLCFA levels (Lee and Raymond, 2013; Braverman et al., 2016). A liver biopsy may be a useful adjunct diagnostic tool to assess the presence or absence and structure of peroxisomes. Definitive diagnosis for all types may require cultured skin fibroblasts for measurement of the levels of VLCFAs and their β -oxidation and, as needed, assay of the peroxisomal steps of plasmalogen synthesis, phytanic acid oxidation, subcellular localization of catalase, enzyme assays, and immunocytochemistry studies. More recently, however, next-generation sequencing panels for the PEX genes are being used for confirmatory diagnostic testing (Braverman et al., 2016). DNA study for deletions also has a role in diagnostic evaluation in some cases as demonstrated by the neonatal presentation of cases with deletion of the *ABCD1* gene on the X chromosome (Corzo et al., 2002; Shimozawa et al., 2011; Iwasa et al., 2013). Diagnostic flow diagrams have been published by Shimozawa et al. (2011) and Klouwer et al. (2015).

Prenatal diagnosis with a variety of methods is available. It can be accomplished in the first or second trimester by biochemical or genetic testing in chorionic villi cells or cultured amniocytes (Waterham and Ebberink, 2012; Klouwer et al., 2015; Braverman et al., 2016). Preimplantation genetic diagnosis can be performed when the PEX mutations are known. Carriers cannot be identified by biochemical testing (Waterham and Ebberink, 2012).

One of the more interesting recent developments in peroxisomal disease is consideration of NBS. The combination of liquid chromatography and tandem mass spectrometry to detect elevated levels of VLCFAs (C26:0-lysophosphatidylcholine) in newborn dried blood spots has been validated as a diagnostic approach for X-ALD (Braverman et al., 2016). Legislation for X-ALD screening has passed in several states. Screening for X-ALD has recently been approved for addition to the Recommended Uniform Screening Panel. NBS for X-ALD should also detect the majority of ZSDs, permitting early diagnosis and intervention (Klouwer et al., 2015; Braverman et al., 2016).

The prognosis for patients with a neonatal-onset peroxisomal disease remains poor, and patients frequently die within the first year of life (Klouwer et al., 2015). Patients with later presentation have a better prognosis but still have progressive disease. Plasma levels of metabolites do not correlate well with disease severity (Klouwer et al., 2015). There is, however, a generally good correlation between the defective PEX gene, the type of mutation, and the impact on peroxisomal assembly and function and the clinical severity (Waterham and Ebberink, 2012).

Treatment for all peroxisomal disorders in the newborn period remains symptomatic and supportive. These disorders are chronic, progressive diseases with no currently available curative therapy. In patients with severe disease, seizure control, feeding, and respiratory support are the main focus of management (Braverman et al., 2016). Feeding difficulties, including malabsorption, are prominent and may require the use of elemental formulas and/or gastrostomy tube placement. Dietary reduction in VLCFAs has not been shown to reduce plasma VLCFA levels as most VLCFAs are produced endogenously (Braverman et al., 2016). In patients with X-ALD, dietary reduction of VLCFAs in combination with supplementation with Lorenzo's oil (a 4:1 mixture of glyceryl trioleate and glyceryl trierucate) can reduce plasma VLCFA levels but does not affect progression of already present leukodystrophy (Braverman et al., 2016). Use of Lorenzo's oil has not been studied in ZSDs but may be contraindicated because of the presence of increased levels of dietary monounsaturated fatty acids in patients who already accumulate large amounts of C26:1 (Klouwer et al., 2015;

Braverman et al., 2016). Because of impaired synthesis of docosahexanoic acid, supplementation with docosahexanoic acid was previously recommended. A placebo-controlled study, however, showed no clinical benefit with supplementation (Parker et al., 2010). Also, because of defective bile acid synthesis, supplementation with the fat-soluble vitamins, A, D, E, and K, is recommended (Braverman et al., 2016). Studies evaluating the effectiveness of bile acid supplementation (cholic acid and chenodeoxycholic acid) are limited, but bile acid supplementation may improve liver function especially in AMACR deficiency (Setchell et al., 2003; Braverman et al., 2016).

Further supportive care includes use of antiepileptic medications for seizure control, oxygen supplementation as needed for respiratory difficulties, use of hearing aids or cochlear implants for hearing loss, use of glasses for vision difficulties, routine dental care, and routine immunizations. Screening for adrenal insufficiency should occur regularly, and replacement therapy should be started as indicated with stress doses when necessary. Citrate therapy may help prevent renal oxalate stones. Bone density and vitamin D status should be monitored. Comprehensive developmental services should be provided. Treatment guidelines have recently been proposed and published by Braverman et al. (2016).

More recently, betaine and arginine have been recognized to be molecular chaperones that can improve peroxisomal assembly and may have a future therapeutic role (Waterham and Ebberink, 2012). HSCT is the established therapy for the cerebral childhood form of X-ALD, but there are no reports describing HSCT in ZSDs (Klouwer et al., 2015). Use of HSCT was recently reported in a young child with acyl-CoA oxidase deficiency. It was considered as a possible disease-arresting therapeutic intervention following recognition that the neuropathologic features of acyl-CoA oxidase deficiency resemble those of X-ALD (Wang et al., 2015). Despite full engraftment, the child experienced neurodegeneration and died in childhood (Wang et al., 2015). Hepatocyte transplantation and orthotopic liver transplantation have been described in patients with infantile Refsum disease with improvement in biochemical parameters and clinical course (Sokal et al., 2003; Van Maldergem et al., 2005). Gene therapy may provide future hope.

Smith–Lemli–Opitz Syndrome

Etiology

SLOS is a well-recognized autosomal recessive malformation syndrome, with an estimated incidence ranging from 1 in 10,000 to 1 in 70,000 in various populations (Smith et al., 1964; Porter, 2008; Cross et al., 2015). In 1993 it was discovered that SLOS is caused by a defect in cholesterol biosynthesis that results in low levels of cholesterol and elevated levels of 7-dehydrocholesterol (7DHC) and its isomer 8-dehydrocholesterol (8DHC) (Irons et al., 1993; Tint et al., 1994). Patients have markedly reduced activity of 7DHC reductase (Honda et al., 1995), the enzyme responsible for conversion of 7DHC to cholesterol encoded by the gene *DHCR7* (Wassif et al., 1998). The cause of the clinical phenotype of SLOS may be related to deficient cholesterol, deficient total sterols, and toxic effects of either 7DHC or compounds derived from it, or a combination of these factors (Bianconi et al., 2015).

Cholesterol is a major lipid component of cellular membranes such as myelin, and it is an important structural component of lipid rafts, which play a major role in intracellular signaling. In animal and in vitro models of SLOS, altered ratios of cholesterol, its dehydrocholesterol precursors, and its derivatives have been

noted to alter membrane rigidity, alter electrostatic properties of biologic membranes that can change the activity of ion-dependent adenosine triphosphatases and channels, decrease the stability of lipid rafts leading to increases in degranulation of mast cells, and reduce ligand binding to receptors such as the serotonin 1A receptor. In addition, bile acids, steroid hormones, neuroactive steroids, and oxysterols are all synthesized from cholesterol, and dehydrocholesterols can also serve as precursors of related steroids, bile acids, and oxysterols that may be antagonists or agonists of the ones derived from cholesterol (Bianconi et al., 2015). Cholesterol is also involved in hedgehog signaling by acting as a cofactor and covalent adduct to hedgehog members (Cooper et al., 2003). Hedgehog is a family of signaling proteins that are critical to pattern formation through interactions with the homeobox genes during embryonic development, and altered hedgehog signaling could explain some malformations seen in SLOS, such as holoprosencephaly and postaxial polydactyly (Farese and Herz, 1998; Kelley and Hennekam, 2000; Cooper et al., 2003). Recently, attention has been drawn to the high sensitivity of 7DHC to oxidation, and thus increased free radical generation may be a possible contributor to certain aspects of the disease, such as retinal degeneration (Chang et al., 2014; Xu and Porter, 2015).

Clinical Features

Recognition of the biochemical defect in SLOS provided the diagnostic test required to recognize the mildest and severest cases, substantially expanding the clinical spectrum of the condition. Classic SLOS is often evident at or before birth; affected patients have prenatal and postnatal growth retardation, microcephaly, and facial dysmorphism, including bitemporal narrowing, ptosis, epicanthic folds, anteverted nares, broad nasal tip, prominent lateral palatine ridges, retromicrognathia, and low-set ears. Other features include two- or three-toe syndactyly (found in 95% of patients), small proximally placed thumbs, occasionally postaxial polydactyly, and cataracts. Males usually have hypospadias, cryptorchidism, and a hypoplastic scrotum but may have ambiguous or female genitalia. Females may have a bicornuate uterus and/or septate vagina. Pyloric stenosis, cleft palate, bifid uvula, pancreatic anomalies, constipation, Hirschsprung disease, renal anomalies, congenital heart defects, and lung segmentation defects have also been reported. Hypotonia progressing to hypertonia is also present. Feeding difficulties and vomiting are common problems in infancy. Irritable behavior and shrill screaming may also pose problems during infancy. Older children frequently have hyperactivity, self-injurious behavior, sleep difficulties, and autistic characteristics. Cranial imaging studies and autopsies show defects in brain morphogenesis, including holoprosencephaly, frontal lobes, cerebellum, and brainstem hypoplasia, irregular gyral patterns, and irregular neuronal organization (Nowaczyk, 1993; Bianconi et al., 2015).

Historically, approximately 20% of patients die within the first year of life, although others may survive for more than 30 years. The clinical severity in SLOS correlates best with either reduction in absolute cholesterol levels or the sum of 7DHC and 8DHC levels expressed as a fraction of total sterol levels (Waterham and Clayton, 2006). Life expectancy appears to correlate inversely with the number and severity of organ defects and with the kinds and numbers of limb, facial, and genital abnormalities (Tint et al., 1995). Developmental outcomes are also highly variable, ranging from severe mental retardation to normal intelligence. Growth is typically lower than in unaffected individuals, and specific growth charts have been developed (Lee et al., 2012). In adults, depression

and anxiety may manifest themselves, and there has at least been one mildly affected female who has undergone a pregnancy with a good outcome (Ellingson et al., 2014). Testing for SLOS has been suggested for all patients with idiopathic intellectual impairment, behavioral anomalies, or both when associated with nonfamilial two- and three-toe syndactyly and failure to thrive (Jezela-Stanek et al., 2008).

Diagnosis

The diagnosis of SLOS is based on findings of elevated levels of 7DHC and 8DHC. False-positive elevations of 7DHC levels occur in patients taking psychoactive medications such as aripiprazole, trazodone, and haloperidol and in patients with increased cholesterol synthesis because of bile acid loss after ileal resection (Bianconi et al., 2015). Plasma cholesterol levels are usually low, but cholesterol is a poor diagnostic marker since as many as 10% of patients at all ages have normal cholesterol levels. Also, in many laboratories, measured cholesterol levels include cholesterol as well as 7DHC and 8DHC (Kelley and Hennekam, 2000).

Confirmation of diagnosis through molecular analysis of *DHCR7* is possible and recommended in cases where the serum concentration of 7DHC is difficult to interpret or prenatal or preimplantation genetic diagnosis is desired. Patients with two null mutations or with mutations in putative loop 8 or 9 have a severer phenotype, and patients with two missense mutations seem to be more mildly affected. However, patients with the same genotype can have markedly different severity (Waterham and Hennekam, 2012). Modifier genes are likely present, and maternal *APOE* and *ABCA1* genotypes that alter maternoplacental cholesterol transfer appear to modify disease severity (Witsch-Baumgartner et al., 2004; Lanthaler et al., 2013). If the genotype is unknown but prenatal testing is desired, abnormal levels of 7DHC from amniotic fluid or tissue from chorionic villus samples can be used for prenatal diagnosis, although false negatives can occur in mild cases. Prenatal sonographic findings of intrauterine growth retardation, increased nuchal translucency, nonimmune hydrops, unusual facial features, cystic hygroma, or major malformations in brain, heart, kidneys, limbs, genitalia, and palate are consistent with SLOS but have low sensitivity and specificity. Maternal serum screening showing low levels of unconjugated estriol, human chorionic gonadotropin, and alpha fetoprotein is also consistent with SLOS (Nowaczyk, 1993).

Treatment

Because of the underlying biochemical defect in SLOS, targeted treatment strategies to date have mainly focused on supplying exogenous cholesterol with the goal of raising cholesterol levels and secondarily lowering 7DHC and 8DHC levels by downregulating the patient's endogenous cholesterol synthesis. Cholesterol is typically given as a dietary modification (egg yolk, breast milk in infants), as a crystalline cholesterol suspension, or as a microencapsulated cholesterol powder with dosing dependent on the formulation ranging from 20 to 300 mg/kg (Irons et al., 1997; Kelley and Hennekam, 2000; Lin et al., 2005). Unfortunately dietary studies on cholesterol supplementation have not been conducted in a randomized fashion except for one short-term study that found no difference in short-term behavior in patients treated with cholesterol supplementation (Tierney et al., 2010). Case series have reported that cholesterol supplementation in SLOS has improved growth, development, and behavior, increased

nerve conduction velocity, and decreased skin photosensitivity, susceptibility to infection, and cholestatic liver disease of infancy when used with and without bile acid replacement. Cholesterol supplementation in SLOS has minimal side effects (Nowaczyk, 1993; Bianconi et al., 2015). However, given that dietary cholesterol does not cross the blood–brain barrier and that SLOS cells have impaired intracellular cholesterol transport, the efficacy of cholesterol supplementation is likely limited (Wassif et al., 2002; Dietschy, 2009).

Other targeted therapies have also been attempted, but none have been validated by controlled studies. Bile acid replacement has been used with cholestatic liver disease in infancy. Fresh frozen plasma, which contains high levels of cholesterol-rich lipoproteins such as LDL, has been used in acutely ill or severely stressed patients and in the setting of fetal intravenous and intraperitoneal transfusion. Stress steroid dosing has been used when there is evidence of adrenal insufficiency. A 3-hydroxy-3-methyl-glutaryl-CoA reductase inhibitor (simvastatin) has been used to improve cholesterol profiles, but its use had to be stopped in one individual who experienced liver dysfunction (Bianconi et al., 2015). Additionally, there may be a role for antioxidants in SLOS since 7DHC is highly reactive and gives rise to biologically active oxysterols (Korade et al., 2014). Direct delivery of cholesterol to the CNS by low-pressure catheter infusions has been proposed but not tested (Yu and Patel, 2005). Gene therapy, the use of neuroactive steroids, and inhibition of glycosphingolipids are also being investigated as possible therapeutic options in SLOS (Merkens et al., 2009).

Even without proven targeted treatments, appropriate supportive management is important. Following the initial diagnosis, to establish the extent of disease and the needs of the individual, recommended evaluations include a developmental assessment, an ophthalmologic evaluation, ECG, echocardiogram, a musculoskeletal evaluation especially for the need for orthotics, a genital urinary examination, nutritional assessment, renal ultrasonography, brain magnetic resonance imaging, hearing evaluation, GI evaluation with special effort to evaluate the patient for pyloric stenosis, gastroesophageal reflux, and Hirschsprung disease if indicated, laboratory evaluation to evaluate the patient for adrenal insufficiency and cholestatic liver disease, and a medical genetics consultation. Referral to early intervention and physical, occupational, and speech therapies is needed in many cases. Surgical interventions, such as gastrectomy tube insertion, surgical repair of cataracts, ptosis, or strabismus, pyloromyotomy, surgical repair of syndactyly or polydactyly, tendon release surgery in cases with significant hypertonia, and tympanostomy may be required in individuals with SLOS. Anesthetic complications of malignant hyperthermia have been reported. Treatment with medications with high affinity for the 7DHC reductase substrate may worsen the biochemical abnormalities so when medications such as haloperidol, trazodone, or aripiprazole are being used, potential benefits need to be weighed against the theoretical risk of worsening the underlying disease. Some infants with severe feeding problems benefit from use of

hypoallergenic, elemental formulas. Patients also need to avoid extended periods of sun exposure and use appropriate sun protection measures given the issue with photosensitivity (Nowaczyk, 1993).
